Family IV. **Nocardiaceae** (Castellani and Chalmers 1919) emend. Zhi, Li and Stackebrandt 2009

MICHAEL GOODFELLOW

No.car.di.a.ce′a.e. N.L. fem. n. *Nocardia* type genus of the family, suff. *-aceae*, ending to denote a family; N.L. fem. pl. n. *Nocardiaceae* the *Nocardia* family.

Aerobic, Gram-stain-positive to Gram-stain-variable, nonmotile actinomycetes which are typically acid–alcohol- or partially acid–alcohol-fast at some stages of the growth cycle. Some strains form an extensively branched substrate mycelium which fragments into coccoid- and rod-shaped elements, others are coccoid or show a rod–coccus/rod–coccus-mycelial growth cycle. Some strains from aerial hyphae. **Chemo-organotrophs with an oxidative metabolism**. Whole-cell hydrolysates are rich in *meso*-diaminopimelic acid, arabinose and galactose. The peptidoglycan is of the A1γ type. **Muramic acid moieties are *N*-glycolated. Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol and phosphatidylinositol mannosides as predominant polar lipids, major proportions of straight-chain saturated, unsaturated and 10-methyloctadecanoic (tuberculostearic) fatty acids though the latter may be found in smaller amounts, and cyclized menaquinones with eight isoprene units. Mycolic acids have 30–64 carbon atoms and up to four double bonds. The fatty acids released on pyrolysis gas chromatography of mycolic acid methyl esters have 12–18 carbon atoms.** The pattern of 16S rRNA signatures consist of nucleotides at positions 250 (U), 316:337 (C–G), 418:425 (C–G), 580:761 (U–A), 559:639 (C–G), 662:743 (C–G), 987:1218 (G–C), and 1000:1040 (A–U). The phylogenetic position of the family *Nocardiaceae*, as determined by 16S rRNA gene sequence analysis, is in the order *Corynebacteriales*.

Members of the family *Nocardiaceae* are widely distributed in aquatic and terrestrial habitats, notably in soil, marine sediments, herbivorous dung and wastewater systems. Some species are opportunistic pathogens for animals, including humans, others are plant pathogens.

DNA G+C content (mol%): 63–73.

Type genus: **Nocardia** Trevisan 1889, 9[AL].

Further descriptive information

Phylogeny. The family *Nocardiaceae* as emended by Rainey et al. (1997) encompassed the genera *Nocardia* and *Rhodococcus*. The subsequent emendation of the family by Zhi et al. (2009) also includes the genera *Gordonia, Millisia, Skermania,* and *Williamsia*; the genus *Smaragdicoccus* Adachi et al. 2007 can be added to this taxon. This broader grouping of genera is essentially based on taxon-specific signatures in 16S rRNA genes. Nevertheless, a case can be made for the continued recognition of the family *Gordoniaceae* Rainey et al. 1997 to encompass the genera *Gordonia, Millisia, Skermania,* and *Williamsia* (see section on the family *Gordoniaceae*), a move which leaves the family *Nocardiaceae* as a home for the genera *Nocardia, Rhodococcus,* and *Smaragdicoccus*. However, the family *Gordoniaceae* may be heterogeneous as the genera *Millisia* and *Skermania* are only loosely associated with the genera *Gordonia* and *Williamsia* based on 16S rRNA gene sequence data. The difficulty in interpreting such phylogenetic trees is a timely reminder that the position of some taxa in actinobacterial 16S rRNA gene trees can be influenced by the strategies employed to construct trees and by the different sequences included in analyses (e.g. Ludwig and Klenk, 2005; Zhi et al., 2009). In such instances there is no sound basis for accepting one tree over another as experience has shown that ambiguities remain in most phylogenetic trees, irrespective of the genes used to construct them. Despite such problems current assignments of genera to families in the order *Corynebacteriales*, like those which preceded them, need to be seen as staging posts leading to better classifications in the future. Indeed, it can be anticipated that suprageneric relationships within the order *Corynebacteriales* based on 16S rRNA gene sequences will need to be reassessed as sequences of novel taxa are added to the existing tree.

Chemotaxonomy. Members of the family *Nocardiaceae* in the sense outlined above share several key chemotaxonomic properties. They have walls rich in *meso*-diaminopimelic acid, arabinose and galactose (wall chemotype IV *sensu* Lechevalier and Lechevalier, 1970), *N*-glycolated muramic acid, a phospholipid pattern containing major amounts of diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, phosphatidylinositol mannosides (phospholipid type 2; Lechevalier et al., 1977, 1981c), a fatty acid profile containing straight chain saturated, unsaturated and 10-methyloctadecanoic (tuberculostearic) acids (fatty acid type 1b; Kroppenstedt, 1985), mycolic acids that fall within the range 34–78 carbon atoms and cyclized menaquinones with eight isoprene units (Adachi et al., 2007; Goodfellow and Maldonado, 2006). This pattern of properties serves to distinguish the family *Nocardiaceae* from corresponding families classified in the order *Corynebacteriales* (see Table 29, in the order *Corynebacteriales*, above). It can also be seen from this table that the constituent genera of the family *Nocardiaceae* can be distinguished by using a combination of chemotaxonomic and micromorphological features, notably on the basis of fatty acid, menaquinone, and mycolic acid composition. Reliable procedures which can be used to detect chemical markers of value in the systematics of mycolic acid-containing genera are highlighted in the section on the order *Corynebacteriales*.

Genus I. **Nocardia** Trevisan 1889[AL]

MICHAEL GOODFELLOW AND LUIS A. MALDONADO

No.card′ia. N.L. fem. n. *Nocardia* named after Edmond Nocard (1850–1903), a French veterinarian who first isolated members of this taxon.

Aerobic, Gram-stain-positive to Gram-stain-variable, nonmotile catalase-positive actinomycetes which are typically acid–alcohol-fast at some stages of the growth cycle. Rudimentary to extensively branched, substrate hyphae that often fragment *in situ* or on mechanical disruption into coccoid to rod-shaped, nonmotile elements. Aerial hyphae, at times visible only microscopically,

are almost always present. Colonial appearance is variable; colonies may be smooth to granular and irregular, wrinkled or heaped. Carotenoid-like pigments confer various shades of orange, pink, red, or yellow to colonies growing on solid culture media. Soluble brown or yellowish diffusible pigments may be produced. **Chemo-organotrophic with an oxidative type of carbohydrate metabolism. Arylsulfatase-negative.** Most strains grow well from 20°C up to 45°C.

Whole-organism hydrolysates are rich in *meso*-2,6 diaminopimelic acid, arabinose, and galactose, and have an A1γ type peptidoglycan. Muramic acid moieties are *N*-glycolated. Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major polar lipids, a hexahydrogenated menaquinone with eight isoprene units where the two end units are cyclized [MK-8(H_4, ω cyclo] as the predominant isoprenologue, and major amounts of straight-chain, saturated, unsaturated. and 10-methyl (tuberculostearic) fatty acids. Mycolic acids have 46–64 carbon atoms and up to four double bonds. The fatty acid esters released on pyrolysis gas chromatography of mycolic acid methyl esters contain 12–18 carbon atoms and can be saturated or unsaturated. *Nocardia*, as determined by 16S rRNA gene sequence analysis, is in the order *Corynebacteriales*.

Nocardiae are widely distributed in aquatic and terrestrial habitats, notably in soils, marine sediments, and wastewater systems. Some species are opportunistic pathogens for animals, including humans.

DNA G+C content (mol%): 63–72% (HPLC, T_m).

Type species: **Nocardia asteroides** (Eppinger 1891) Blanchard 1896, 856[VP].

Further descriptive information

Phylogeny. The genus *Nocardia* is classified in the order *Corynebacteriales*, formerly suborder *Corynebacterineae* (Stackebrandt et al. 1997) Zhi et al. 2009, based on 16S rRNA signatures and shares similar chemotaxonomic characteristics with genera assigned to the order, notably the presence of mycolic acids (Adachi et al., 2007; Goodfellow et al., 1999; Goodfellow and Maldonado, 2006). The taxon is the type genus of the family *Nocardiaceae* (Castellani and Chalmers, 1913) emended Stackebrandt et al., (1997) which also contains the genus *Rhodococcus*, and according to Zhi et al. (2009), the genera *Gordonia* (*ex* Tsukamura, 1971) Stackebrandt et al., (1989) (effective publication Stackebrandt et al., 1988), *Millisia* (Soddell et al., 2006a), *Skermania* (Chun et al., 1997), *Smaragdicoccus* Adachi et al. 2007, and *Williamsia* (Kämpfer et al., 1999).

The genus contains 75 validly published species, most of which have been delineated over the past 10 years using a combination of genotypic and phenotypic criteria (Jurado et al., 2008; Kaewkla and Franco, 2010; Yassin et al., 2001a, 2001b; Zhang et al., 2003). Most of these novel species were associated with human infections (Conville et al., 2008; Kageyama et al., 2004b, 2004c, 2004d, 2004e, 2004f, 2004g, 2004h, 2004i; Rodriguez-Nava et al., 2004) with nearly all of the remaining ones isolated from soil collected from different geographical locations (Kämpfer et al., 2007; Maldonado et al., 2000; Saintpierre-Bonaccio et al., 2004). It is evident from the 16S rRNA *Nocardia* gene tree (Figure 88) that the type strains of well established pathogenic species, including *Nocardia asteroides, Nocardia crassostreae, Nocardia farcinica, Nocardia nova*, and *Nocardia otitidiscaviarium* (formerly *Nocardia caviae*), are scattered across the clade and in some cases are most closely related to soil isolates.

The importance of high quality nocardial 16S rRNA gene sequences was highlighted by Roth et al. (2003) who provided a molecular basis for accurate species identification, including taxa assigned to the *Nocardia asteroides* complex. They confirmed that the interspecies heterogeneity between closely related species can be low; found that sequence diversity is less than 5 bases in 8 out of 11 species where more than one strain had been studied; showed that at least 10 taxa merit description as new species, and noted that some subclades contain strains with distinct antimicrobial profiles based on the six drug patterns recognized by Wallace et al. (1988). Strains previously classified as *Nocardia asteroides* were assigned to four distinct phylogenetic groups, namely, the cluster containing the type strain (*Nocardia sensu stricto*), *Nocardia abscessus, Nocardia cyriacigeorgica* and to taxa closely related to either *Nocardia carnea* or *Nocardia flavorosea*. The *Nocardia abscessus, Nocardia cyriacigeorgica*, and the latter two subclades were equivalent to drug patterns I, VI, and II of Wallace and his colleagues. Drug patterns III and IV were shown by strains belonging to the *Nocardia nova* and *Nocardia farcinica* subclades, respectively. However, the discovery that some *Nocardia nova* isolates have different 16S rRNA genes emphasizes the need to carefully interpret 16S rRNA gene sequence data especially between closely related species (Conville and Witebsky, 2005).

The type strains of the two most closely related species, *Nocardia kruczakiae* and *Nocardia veterana*, share a 16S rRNA gene sequence similarity of 99.8% and a DNA–DNA relatedness value of 55±8.5% (Conville and Witebsky, 2005), a figure below the 70% threshold recommended for the circumscription of bacterial species (Wayne et al., 1987). In contrast, the type strains of the most distantly related species, *Nocardia coubleae, Nocardia cummidelens*, and *Nocardia pigrifrangens* each share a 16S rRNA gene sequence similarity of 93.1%. Several multimembered taxa supported by high bootstrap values can be seen in the nocardial tree (Figure 88). These include the *Nocardia africana, Nocardia beijingensis, Nocardia carnea*, and *Nocardia salmonicida* subclades, all of which include strains assigned to species isolated from clinical material and from soil. DNA–DNA relatedness data have played a pivotal role in distinguishing between closely related *Nocardia* species (Conville et al., 2008; Kageyama et al., 2004b, 2004c, 2004d, 2004e, 2004f, 2004g, 2004h, 2004i; Kinoshita et al., 2001; Kudo et al., 1988; Lamm et al., 2009).

Conville et al. (2006) have shown that sequence analysis and alignment of a 468-bp region of the *secA1* gene gives greater resolution between closely related *Nocardia* species than does the corresponding 16S rRNA gene sequence data. They found that the sequence similarities of type and reference strains to their nearest species were in the range 85.0–98.7% for the *secA1* gene compared with 94.4–99.8% for the corresponding 16S rRNA gene sequences. The type strains of *Nocardia kruczakiae* and *Nocardia veterana*, for instance, showed a sequence diversity with the *secA1* gene of 91.9% compared with a 16S rRNA gene sequence similarity of 99.8%. Similarly, alignment of deduced amino acid sequences (composed of 156 amino acid residues) of the 468-bp *secA1* gene region showed good separation of type and reference *Nocardia* strains. Indeed, each type or reference strain shared a unique sequence with similarities between the

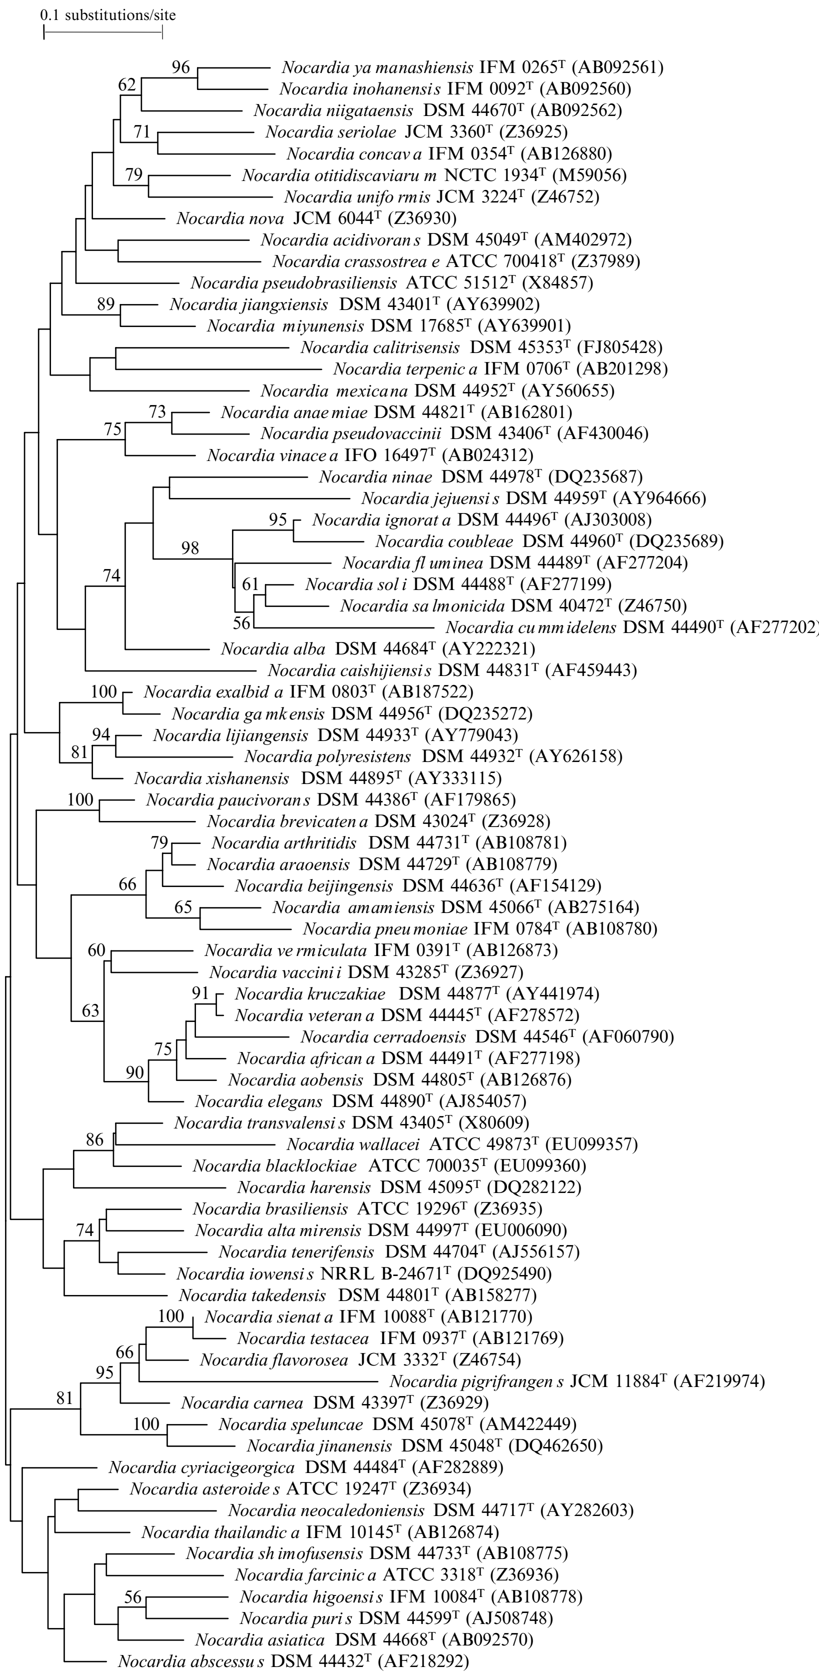

FIGURE 88. Neighbor-joining tree (Saitou and Nei, 1987) based on nearly complete 16S rRNA gene sequences showing relationships between *Nocardia* species. Numbers at the nodes indicate levels of bootstrap support (Felsenstein, 1985) based on an analysis of 1000 resampled datasets. Only values over 55% are given. Bar = 0.1 substitutions per nucleotide position.

strains ranging from 91% (14 amino acid differences) to 99.4% (single amino acid difference). The *secA1* protein is an essential component of the preprotein translocase ATPase which is involved in the export of proteins across bacterial cytoplasmic membranes (Schmidt and Kiser, 1999).

Cell morphology. Nocardiae do not have any distinctive morphological features other than the ability to form aerial hyphae which fragment into coccoid and rod-like elements (Locci, 1976; Nesterenko et al., 1978b; Williams et al., 1976). These workers found that the development and stability of aerial and substrate mycelia is influenced by the organisms and the conditions used to cultivate them. It is clear that micromorphological observations are sensitive to the techniques chosen for specimen preparation and the methods chosen to examine them (Locci, 1976).

The most detailed morphological studies were carried by Locci (1976) who showed that the growth cycle of nocardiae is an intricate process with stages that are difficult to decipher. Generally cocci (Plate 1, parts 1 and 2) and rods (Plate 1, parts 3–7) germinate by forming one or two germ tubes at the extremities of rods and at points along the long axis of the hypha that give rise to cocci. However, in each case, the germ tubes tend to converge almost immediately from the main axis of the parent hypha (Plate 1, parts 1–7). A true mycelial stage is now formed albeit for varying periods of time depending on the strain, substrates, and a number of environmental factors (Plate 1, parts 8 and 9). At this stage, hyphal tips are flexible and tend to change directions thereby determining the configuration of the microcolony (Plate 1, parts 9 and 11). Next, hyphae lose their cytoplasmic continuity and divide transversely giving rise to segments. This process usually takes place quite rapidly and yields rods that are more or less regular in size (Plate 1, parts 10–12). Rods may divide further giving rise to cocci. Each rod and coccoid-like element that is formed from a fragmenting microcolony has the potential to germinate thereby ensuring the further development of the microcolony into a macroscopic colony.

Aerial mycelia are formed from both individual hyphae and from independent fragments (Plate 2, part 1). The extent to which aerial hyphae are formed ranges from sparse to abundant. In *Nocardia asteroides* and *Nocardia farcinica* aerial hyphae tend to form synnemata which coalesce even when borne in relatively distant regions with the consequent appearance of hyphal bridges at the base of many synnemata (Plate 2, parts 2–4). Aerial hyphae whether isolated or grouped together may fragment into spore-like structures. The fragments usually retain a rod-like appearance, but are generally irregular in shape and size (Plate 2, parts 5 and 6). However, a few nocardiae form well-developed spores, as exemplified in Figure 89 and Figure 90. Short chains of spores are produced on the aerial mycelium of *Nocardia aobensis* (Kageyama et al., 2004d), *Nocardia asiatica* (Kageyama et al., 2004b), *Nocardia callitridis* (Kaewkla and Franco, 2010), *Nocardia inohanensis* (Kageyama et al., 2004i), *Nocardia niigatensis* (Kageyama et al., 2004i), and *Nocardia takedensis* (Yamamura et al., 2005). *Nocardia brevicatena* is unusual as it forms distinctive oval to round spores in short chains on both aerial and substrate mycelia (Lechevalier et al., 1961).

Colony morphology. Nocardiae grow well on standard agar media used to cultivate filamentous actinomycetes. Smooth to rough, convex to irregular colonies with filamentous margins are formed on glucose-yeast extract agar (Gordon and Mihm, 1962; Maldonado et al., 2000). Colonies are 0.3–3.0 mm in diameter and show a range of colors, including beige, brown, buff, orange, pink, red, and yellow. Soluble pigments, when present, are usually brown or yellow.

Chemotaxonomy. Nocardiae have cell walls rich in *meso*-diaminopimelic acid, arabinose, and galactose (Goodfellow et al., 1999; Michel and Bordet, 1976; Sun et al., 2009; Yamamura et al., 2007), that is, they have a wall chemotype IV *sensu* Lechevalier and Lechevalier (1970), an A1γ peptidoglycan (Schleifer and Kandler, 1972), and *N*-glycolated muramic acid moieties (Gürtler and Mayall, 2001; Uchida and Aida, 1979b, 1979a; Uchida et al., 1999; Uchida and Seino, 1997). They contain major amounts of diphosphatidylglycerol, phosphatidylethanolamine (a taxonomically significant nitrogenous phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides and hence have a phospholipid pattern II after Lechevalier et al. (1977, 1981c) with a variable distribution of phosphatidylglycerol (Kämpfer et al., 2007; Minnikin et al., 1977), predominant amounts of hexahydrogenated menaquinones with eight isoprene units where the two terminal units are cyclized (Collins et al., 1987; Howarth et al., 1986; Sun et al., 2009; Yassin et al., 2000a), and a DNA G+C content of 63–72 mol%. Nocardiae also contain characteristic lipid soluble, iron binding compounds, the nocobactins (Ratledge and Patel, 1976).

Simple fatty acids and mycolic acids of *Nocardia* strains have been used extensively as taxonomic markers (Goodfellow and Maldonado, 2006; Minnikin and Goodfellow, 1976, 1980). Nocardiae typically contain major amounts of straight-chain saturated and unsaturated fatty acids and significant amounts of tuberculostearic acid (i.e., they have a type II fatty acid profile as defined by Kroppenstedt, 1985) and mycolic acids with 46–64 carbon atoms and up to four double bonds (Alshamaony et al., 1976a; Hoshino et al., 2007; Minnikin and Goodfellow, 1980; Yassin et al., 2000a; Yassin et al., 2000b). In general, nocardiae have similar qualitative fatty acid profiles though quantitative differences in cellular fatty acid composition has been used to distinguish between closely related species (Hoshino et al., 2007; Kageyama et al., 2004b, 2004c, 2004d, 2004e, 2004f, 2004g, 2004h, 2004i; Kämpfer et al., 2007). *Nocardia asteroides* can adapt to changes in temperature by altering the structure of mycolic acids in the cell wall (Tomiyasu, 1982).

One dimensional thin-layer-chromatography of nocardial whole-organism methanolysates usually reveals two lipid spots: one corresponds to mycolic acids (R_f value around 0.47) and the other (R_f 0.91) to nonhydroxylated fatty acids (Minnikin et al., 1975; Yassin and Brenner, 2005; Yassin et al., 2000a, 2000b, 2003). However, a second mycolic acid spot has been detected in a few *Nocardia* species, including *Nocardia abscessus, Nocardia asiatica, Nocardia beijingensis,* and *Nocardia exalbida* (Iida et al., 2006; Kageyama et al., 2001, 2004b; Poonwan et al., 2005).

The cell envelopes of nocardiae are complex; they contain a thick peptidoglycan, sugars, and are rich in lipids, notably mycolic acids (Minnikin, 1982). Ester bonds connect mycolic acids with an arabinogalactan which is attached to the peptidoglycan. The outer mycolic acid layer probably has the same function as the outer membrane of Gram-stain-negative bacteria, which contain channel-forming proteins, the porins, for the passage of hydrophilic solutes. Very little is known about the molecular basis of the permeability of nocardial cell walls, although porins have been detected in the mycolic acid layer

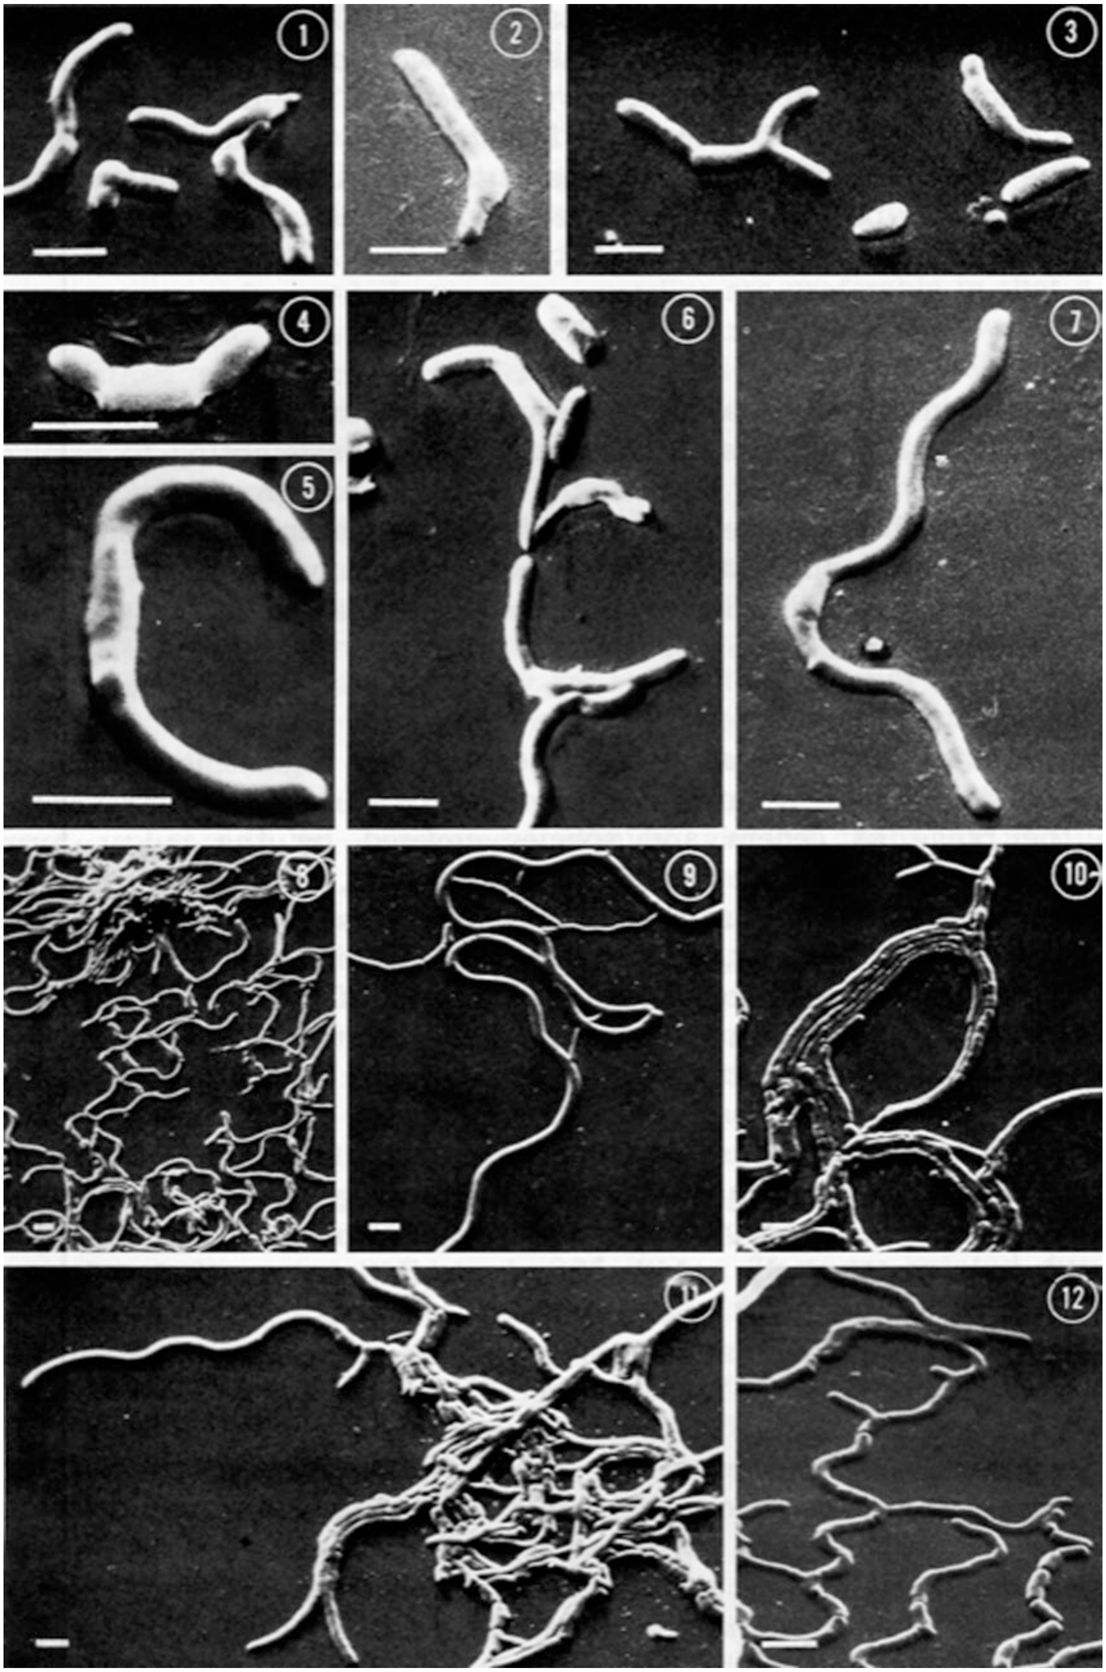

PLATE 1. *Nocardia farcinica* IPV 2119: propagule germination (parts 1–7), microcolonies (parts 8–11) and initial fragmentation (parts 11–12); bars = 2 μm. (Reproduced with permission from Locci 1976. *Actinomycetes: the Boundary Microorganisms*. Toppan, Tokyo.)

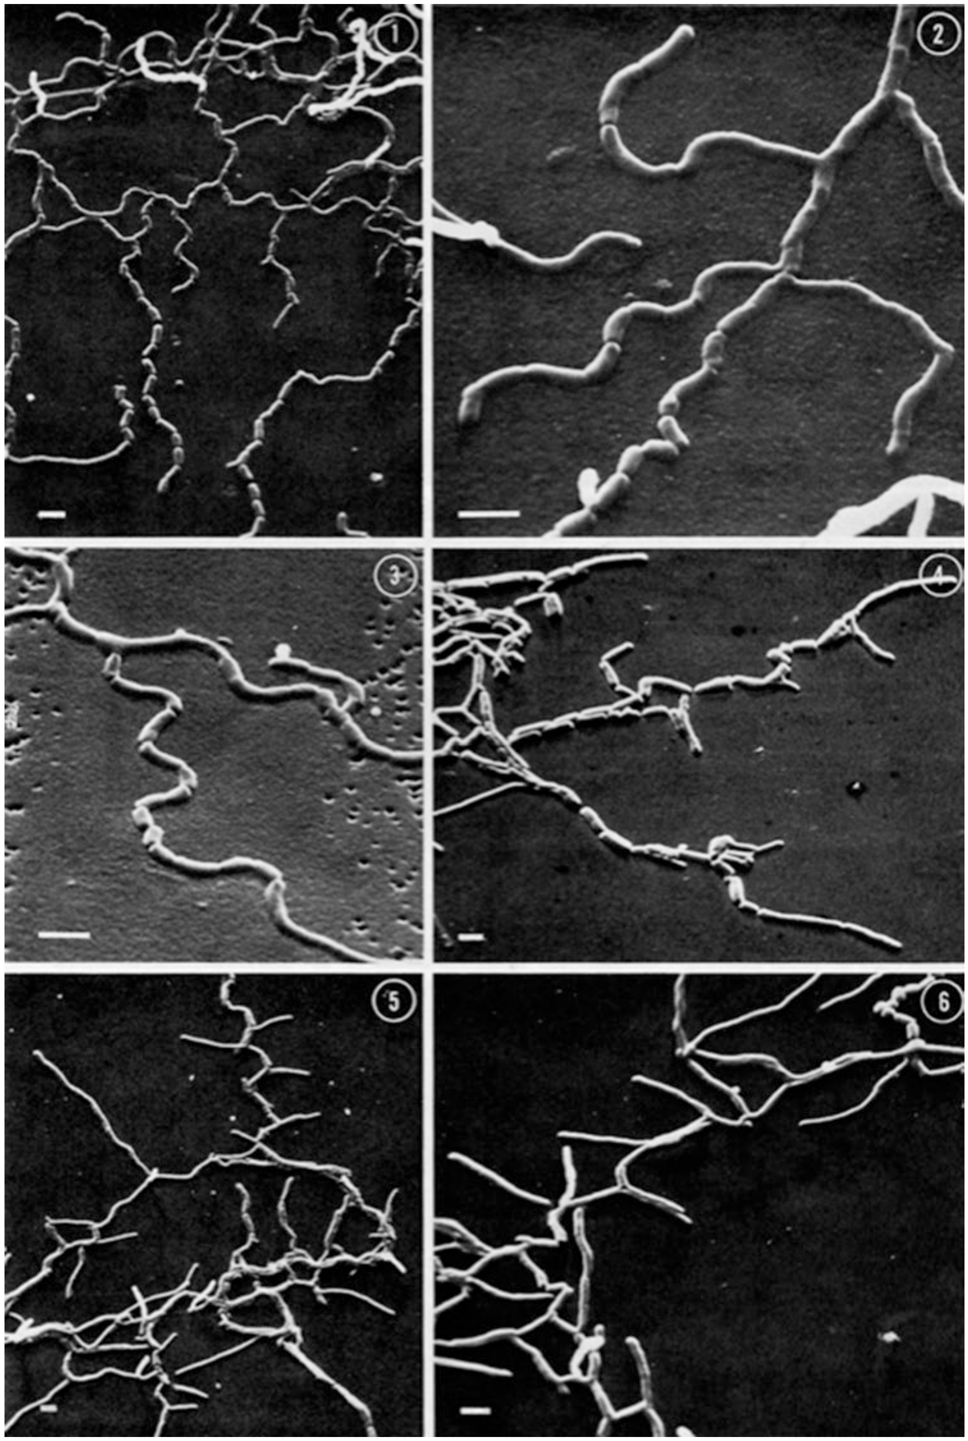

PLATE 2. Hyphal fragmentation (parts 1–3) and germination of fragments (parts 4–6) in *Nocardia farcinica* IPV 2110; bar = 2 µm. (Reproduced with permission from Locci. 1976. *Actinomycetes: the Boundary Microorganisms*. Toppan, Tokyo.)

of *Nocardia asteroides* and *Nocardia farcinica* (Riess et al., 1998; Riess et al., 1999). The cell wall of the *Nocardia asteroides* strain contains an 84-kDa channel-forming protein. It was shown that the cell wall activity of this strain was controlled by negatively charged groups at the channel mouths, indicating that porins are preferentially permeable to cations. The channels were also shown to exhibit asymmetric voltage dependence.

Fine structure. As mentioned earlier, nocardiae typically form branched filaments which fragment into rods and cocci. There have been innumerable light microscope observations of the developmental process (McClung, 1949, 1954a, 1955; McClung and Uesaka, 1961), but very few ultrastructural investigations since the pioneering work of Kawata and Inoue (1965) and Farshtchi and McClung (1967), apart from the extensive

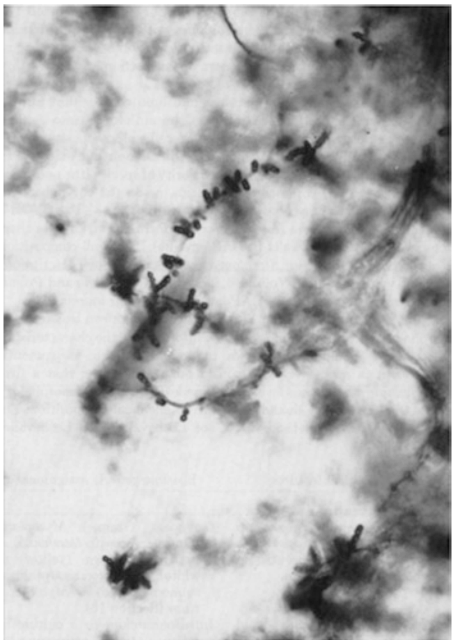

FIGURE 89. Aerial spore chains of *Nocardia brevicatena* (× 1250). (Reprinted from the 1st edition of *Bergey's Manual of Determinative Bacteriology*.)

work of Blaine Beaman and his colleagues (Beaman, 1968, 1973, 1975, 1976, 1982, 1984, 1993; Beaman and Beaman, 1994; Beaman and Ogata, 1993; Beaman et al., 1978). Transmission electron microscopy has shown that some nocardiae have a trilaminar cell-wall structure (Beadles et al., 1980; Beaman, 1975; Friedman et al., 1998), as exemplified in Figure 91.

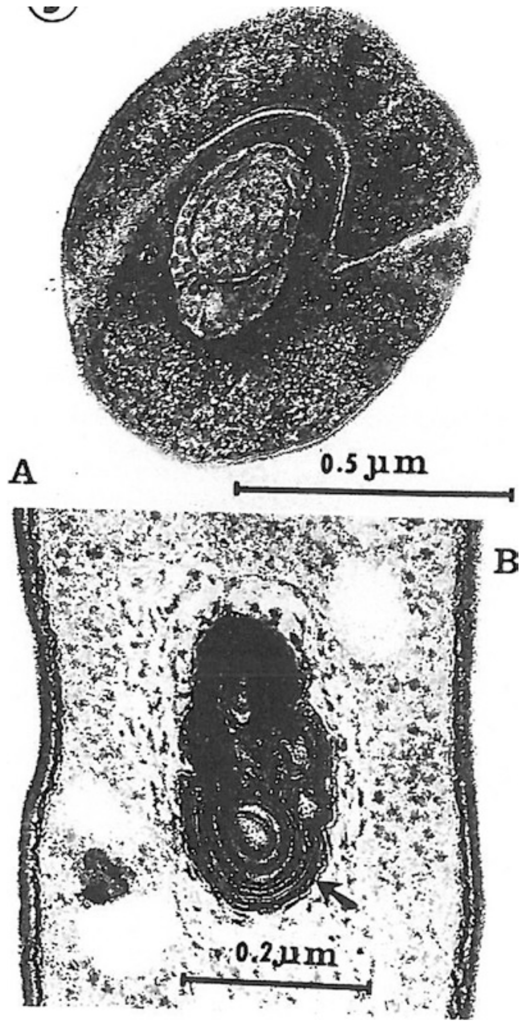

FIGURE 91. Comparative ultrastructural appearance of *Nocardia asteroides* GUH.2 (Beaman) grown *in vitro* (brain heart infusion broth [BHI]) and *in vivo* (mouse tissues). A. Cell grown to mid-exponential phase in BHI broth showing the characteristic tri-layered cell wall (short arrow) and a large laminar mesosome (*arrow*). B. Cell 12 d post-inoculation into the peritoneal cavity of a mouse showing large lipid inclusions (V) and simple vesicular membrane inclusions (*arrow*). A and B are at the same magnification. (Reproduced with permission from Beaman. 1978. Zentralbl. Bakteriol. Parasitenkd. Infektionskr. Hyg. 1. Abt. Suppl. 6, 201–220.)

Beaman and Shankel (1969) showed that as *Nocardia* strain 721-A aged a dark staining inner layer of peptidoglycan and neutral sugars thickened while a light staining outer layer rich in lipids and proteins became more diffuse. Likewise, the amount of peptidoglycan in the cell wall has been shown to increase and the lipid content decrease (Beaman, 1975). Beadles et al. (1980) showed that *Nocardia asteroides* and *Nocardia brasiliensis* strains contained cell membranes, as well as trilaminar cell walls. They showed that the thickness of the cell wall layers, especially the inner peptidoglycan layer, varied between strains, a phenomenon that could be correlated with their virulence and diverse pathogenicities. Beaman (1973) demonstrated a similar relationship *in vivo* between the inner cell walls of a strongly virulent strain, *Nocardia asteroides* Mahve, and a weakly virulent organism, *Nocardia asteroides* 10905, when these

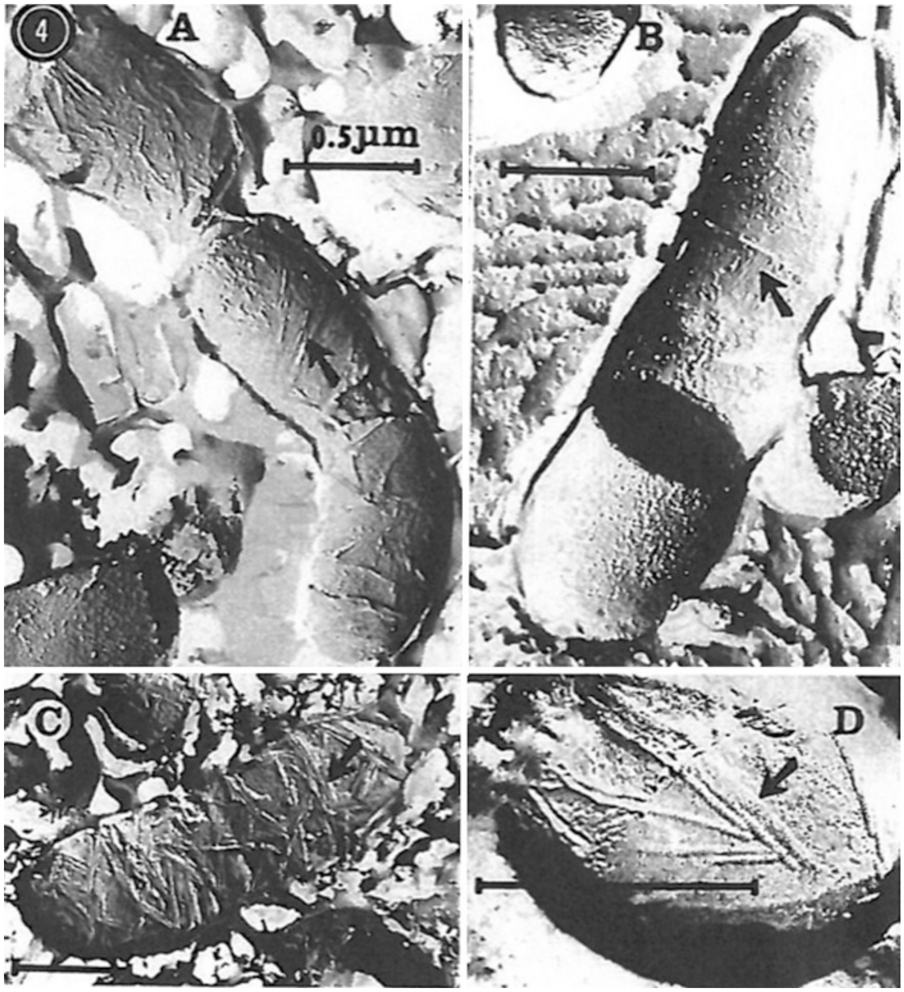

FIGURE 92. Thin section of a exponential phase cell of *Nocardia otitidis-caviarium* (formerly *Nocardia caviae*) strain 260 grown in brain heart infusion broth at 34°C showing the presence of a tubulovesicular mesosome. B. *Nocardia asteroides* strain 10905 grown in brain heart infusion broth showing a large lamellar mesosome embedded in the nuclear material. The cells shown in A and B were grown under the same conditions and fixed using the same chemicals. (Reproduced with permission from Beaman. 1978. Zentralbl. Bakteriol. Parasitenkd. Infektionskr. Hyg. 1. Abt. Suppl. 6, 201–220.)

strains were observed in infected mouse tissue (Figure 91). It was concluded that these quantitative differences in peptidoglycan might govern the ability of strains to resist degradation by phagosomal hydrolases, especially lysozyme.

L-Forms have been isolated from several pathogenic nocardiae *in vitro* by inducing protoplasts and sphaeroplasts with glycine plus lysozyme (Beaman, 1976). Some nocardiae appear to be more susceptible to L-form conversion than others, thereby suggesting chemical differences in the cell-wall structure between the various strains tested (Bourgeois, 1975; Bourgeois and Beaman, 1975). Some cell wall deficient nocardiae may be either pathogenic or persist within a host in a latent form for up to a year, thereby showing that intact cell-wall structure is not essential for pathogenicity (Beaman, 1980).

Serrano et al. (1971) used shadowing and negative staining methods to show that the outer surface of *Nocardia asteroides* strains, including ATCC 14957, was covered by many irregular staining fibers; freeze-dried replicas confirmed these observations (Beaman et al., 1978; Williams et al., 1976). Serrano and his colleagues also observed coccoid, bacillary, and filamentous forms in ultrathin sections of *Nocardia asteroides* ATCC 14957; the walls of the bacillary forms were 10–20 mm thick and contained mesosomes. *Nocardia asteroides* strains generally contain lamellar mesosomes, and *Nocardia brasiliensis* and *Nocardia otitidiscaviarum* tuberculovesicular mesosomes (Beaman et al., 1978; Figure 92).

Nocardiae typically contain lipid inclusions and metachromatic granules (Farshtchi and McClung, 1967; Serrano et al., 1974; Williams et al., 1976) though the accumulation of these materials is influenced by the strain, the age of the culture, and the growth medium (Dispersio and Deal, 1974). Lipid inclusions are readily observed by light microscopy following staining with Sudan Black B and metachromatic granules by light microscopy following staining with methylene blue or toluidine blue. Transmission electron microscopy of thin sectioned preparations show lipid inclusions as electron-lucent, spherical

regions within cells (Beaman et al., 1978), as shown in Figure 91. *In vivo* grown cells of *Nocardia asteroides* usually contain large lipid inclusions which give cells a pronounced beaded appearance when stained for light microscopy (Beaman, 1973).

Nutritional and growth conditions. *Nocardia* strains grow well on most standard media, such as glucose-yeast extract (Gordon and Mihm, 1962), brain heart infusion (Difco), modified Bennett's (Jones, 1949), modified Sauton's (Mordarska et al., 1972), Sabouraud glucose and yeast extract-malt extract (Shirling and Gottlieb, 1966) agars, and on Mueller–Hinton II medium supplemented with glucose (Kageyama et al., 2004b, 2004c, 2004d, 2004e, 2004f, 2004g, 2004h, 2004i). Acetate, glucose, and propionate are used as sole carbon sources, and amino acids, ammonia, and nitrate as simple nitrogen sources; more complex nitrogen sources, such as meat, soy, or yeast peptones and hydrolysates, are also utilized. Doubling times, as for most actinomycetes, are longer than for other bacteria: a generation time of 5.5 h has been reported for *Nocardia asteroides* and *Nocardia brasiliensis* strains (Beadles et al., 1980). Some strains grow to stationery phase in 3–7 d, others grow more slowly.

Metabolism. Nocardiae are aerobic, catalase-positive, chemo-organotrophic actinomycetes which have an oxidative metabolism. They degrade a broad range of organic substrates, and metabolize many sole carbon compounds and carbon and nitrogen compounds (Conville et al., 2008; Goodfellow, 1971; Gordon and Mihm, 1957; Gordon et al., 1978; Kämpfer et al., 2004; Kim et al., 2002b; McClung, 1954b; Orchard and Goodfellow, 1980). However, relatively little is known about their metabolic properties, partly due to the early difficulties in establishing the taxonomic status of strains. Indeed, it is now clear that organisms belonging to other taxa possess many of the metabolic properties attributed to "nocardiae", notably members of the genera *Amycolatopsis* (Arai et al., 1988; Cain, 1981; Matsushima et al., 1987; Schupp et al., 1975; Tárnok, 1976), and *Gordonia* and *Rhodococcus* (Bradley, 1978; Brownell and Denniston, 1984; Peczynska-Czoch and Mordarski, 1988; Raymond and Jamison, 1971; Tárnok, 1976).

The complete genome sequence of *Nocardia farcinica* IFM 10152, a clinical isolate, shows that it has extensive metabolic capabilities (Ishikawa et al., 2004); it contains at least 103 oxygenases, 27 of which are putative cytochrome P450 monoxygenases. This strain was considered to have a higher metabolic potential than *Pseudomonas putida* KT2240, an organism which contains 37 oxygenases (Nelson et al., 2002).

Some nocardiae, including clinically significant isolates, produce industrially significant enzymes (Coco et al., 2001; Lamm et al., 2009) and bioactive metabolites (Hoshino et al., 2004a, 2004b; Mikami et al., 1992). The type strain of *Nocardia iowensis* (formerly *Nocardia* strain NRRL 5646) was initially identified as an antibiotic-producing organism (Hlavka and Bitha, 1977; Martin et al., 1977) but was subsequently shown to be remarkably metabolically versatile. It converts many natural and synthetic compounds into valuable products, including carnosic acid derivatives (Hosny et al., 2002), flavanoids (Herath et al., 2006; Maatoog and Rosazza, 2005), vanillic acid (Dhar et al., 2007), and 4-vinylphenol (Lee and Rosazza, 2004). It transforms quinovic acid glycosides (Cheng et al., 2004) and is the source of a novel ATP/NADPH-dependent carboxylic acid reductase (Li and Rosazza, 1997); the gene encoding the latter has been cloned (He et al., 2004a). The reduction system requires a phosphopantetheinyl transferase (Venkitasubramanian et al., 2007).

Strain NRRL 5646^T contains the first nitric oxide synthase (NOS) system characterized in prokaryotes (Chen and Rosazza, 1994, 1995). As part of this system, it produces guanylate cyclase for cyclic GMP synthesis (He and Rosazza, 2003; Son and Rosazza, 2000) and GTP cyclohydrolase I (He et al., 2004b) for tetrahydrobiopterin biosynthesis. Thiol formation and the detection of mycothiol-dependent dehydrogenase activity in cell extracts of strain NRRL 5646^T are relevant to the possible modulation of nitric oxide (Lee et al., 2007).

Some nocardiae are the source of interesting secondary metabolites such as anti-coumacin B, which targets bone morphogenetic protein-2, from *Nocardia jinanensis* (Sun et al., 2009), nocardicins from *Nocardia uniformis* (Aoki et al., 1976; Hosoda et al., 1977), and tubelactomicin A, a new 16-membered lactose antibiotic from *Nocardia vinacea* (Kinoshita et al., 2001). Several new bioactive compounds have been detected from clinically significant *Nocardia* strains. These include asterobactin, a new siderophore group, from *Nocardia asteroides* (Nemoto et al., 2002), a toxic substance from *Nocardia otitidiscaviarum* (Mikami et al., 1990), novel terpenoid immunosuppressive antibiotics from *Nocardia terpenica* (Hoshino et al., 2007; Tanaka et al., 1997a), transvalecin A, a new thiazolidine-type antibiotic from *Nocardia transvalensis* (Hoshino et al., 2004a; Hoshino et al., 2004b), and the nocathiacins, new thiazolyl peptide antibiotics from a *Nocardia* strain (Leet et al., 2003; Li et al., 2003).

Nocardia brasiliensis has been shown to be a particularly rich source of bioactive compounds, as exemplified by the discovery of brasilidine A, a cytotoxic indole alkaloid (Imai et al., 1997; Kobayashi et al., 1997), brasilicardin A, a new terpenoid antibiotic (Komaki et al., 1998; Shigemori et al., 1998), brasilinolide A, a new immunosuppressive macrolide (Shigemori et al., 1996; Tanaka et al., 1997b), brasiliquinones A ~ C, novel cytotoxic benz [a] anthroquinones (Nemoto et al., 1997; Tsuda et al., 1996), a new mutactinomycin derivative (Mikami et al., 1992), nocardicyclines A and B, new anthracyline antibiotics (Tanaka et al., 1997a), and brasilibactin A, a novel cytotoxic compound (Tsuda et al., 2005).

The anthraquinone chrysophanol is the first secondary metabolite known to be synthesized in an organism-specific way, namely through different folding mechanisms (Bringmann et al., 2006). These workers found that *Nocardia* strain Acta 1057, an isolate from a hay meadow soil, produced chrysophanol through folding mode S, whereas eukaryotes (insects, fungi, and plants) use folding mechanism F. A third folding mode, S′, was discovered in *Streptomyces* strain AK 671 (Bringmann et al., 2009).

Genetics. Genetic recombination and plasmids have been detected in *Nocardia asteroides* (Kasweck and Little, 1982; Kasweck et al., 1981, 1982). Plasmids have also been detected in pathogenic strains of *Nocardia* (Ishikawa et al., 2004; Provost et al., 1996). The inability of Provost and his colleagues to detect plasmids in most of the strains they studied suggests that these elements are not directly involved in virulence. They were able to demonstrate a statistically significant correlation between the localization of cutaneous infections and the incidence of plasmid-bearing strains, but were unable to relate

the presence of plasmids to individual phenotypic traits. Xia et al. (2006) characterized one of the smallest circular plasmids found in *Nocardia* strains, namely plasmid PXT 107 from *Nocardia* strain 107. The complete sequence of this plasmid consists of 4335 bp and encodes a replication extragenic palindromic (Rep) protein and six hypothetical proteins. It was also shown that the *Escherichia coli–Nocardia* shuttle vector pHAQ22, which contains the rep gene of PXT107, propagates in *Nocardia*, but not in *Streptomyces*.

Nocardiophages have been reported for *Nocardia asteroides* (Andrejzewski et al., 1978; Andrzejewski and Pietkiewicz, 1972; Prauser, 1976, 1981a; Pulverer et al., 1975), *Nocardia brasiliensis* (Pulverer et al., 1974), *Nocardia carnea* (Williams et al., 1980), and for *Nocardia otitidiscaviarum* and *Nocardia vaccinii* (Prauser, 1976). Members of the family *Nocardiaceae* are usually susceptible to nocardiophage, unlike strains assigned to the families *Mycobacteriaceae* and *Pseudonocardiaceae* (Prauser, 1981a; Williams et al., 1980). Conversely, phages that lyse *Amycolatopsis mediterranei* are inactive against nocardiae (Thiemann et al., 1964).

The complete genome of *Nocardia farcinica* IFM 10152 (Ishikawa et al., 2004) consists of a single circular chromosome (6,021,225 bp) with a mean G+C content of 70.8 mol%, and plasmids pNF 1 (184,027 bp) and pNF2 (87,093 bp) with mean G+C contents of 67.2 and 68.4 mol%, respectively. The chromosome, which encodes 5,674 putative protein-coding sequences, 53 tRNA genes, and 3 copies of rRNA operons, contains many candidate genes for virulence, multidrug resistance, and secondary metabolites. In addition, plasmids pNF1 and pNF2 encode 160 and 90 predicted protein-coding sequences, respectively. An analysis of paralogous protein families suggests that gene duplication gives the organism the capacity to survive both in the soil ecosystem and in animal tissues. Further analysis of the genome sequence can be expected to provide other insights into the molecular basis of the versatility of *Nocardia farcinica* IFM 10152.

Antibiotic sensitivity patterns. Studies on the antibiotic sensitivity patterns of nocardiae have been driven by clinical (Brown-Elliott et al., 2001; Septimus and Wallace, 1986; Vera-Cabrera et al., 2004; Welsh and Vera-Calera, 2003) and taxonomic considerations (Boiron and Provost, 1988b, 1988a; Goodfellow and Orchard, 1974; Gutmann et al., 1983; Wallace and Steele, 1988; Wallace et al., 1983). In general, nocardiae are sensitive to antibacterial agents such as aminoglycosides, sulfonamides, and tetracyclines, less so to cephalosporins, penicillins, and peptide antibiotics (Goodfellow and Lechevalier, 1989). Sulfonamides, notably the combination of sulfamethoxazole and trimethoprim, are often the agents of choice for the treatment of actinomycetoma and nocardiosis (Wallace et al., 1983), though optimal antimicrobial therapy for patients with nocardiosis has yet to be established (Brown-Elliott et al., 2006; McNeil et al., 1990). Other antimicrobial regimes used to treat nocardial infections have been reviewed by Brown-Elliott et al. (2006).

The susceptibility of 78 geographically diverse, clinical isolates of *Nocardia asteroides* to 12 antimicrobial agents, including aminoglycosides, ciprofloxacin, erythromycin, and β-lactams, was determined by Wallace et al. (1988) using a microdilution procedure. A limited number of patterns of susceptibility to all drug classes was identified, with 95% of isolates exhibiting one of five patterns (types 1–5). The largest group (35% of isolates) contained strains resistant to ampicillin, but susceptible to imipenem and broad-spectrum cephalosporins. Other groups encompassed isolates resistant to ampicillin and erythromycin (18%), to the cephalosporins (17%), and to ampicillin and carbenicillin with intermediate sensitivity to imipenem (17%). The most active parenteral agents were amikacin (95%), imipenem (88%), ceftriaxone (82%), and cefotaxime (88%) and the most effective oral agents were the sulfonamides (100%), minocycline (100%), and ampicillin (40%).

The taxonomic significance of the work outlined above was subsequently found to be in line with the taxonomic significance of previous studies in which pathogenic strains of *Nocardia asteroides, Nocardia brasiliensis, Nocardia farcinica*, and *Nocardia otitidiscaviarum* were found to have different drug susceptibility patterns (Boiron and Provost, 1988b, 1988a; Goodfellow and Orchard, 1974; Wallace et al., 1987; Wallace et al., 1983). Thus, *Nocardia asteroides* complex strains resistant to ceftriaxone, cefotaxime, and ceframandole (type 5) were equated with *Nocardia farcinica* (Wallace et al., 1990), and those resistant to ampicillin and erythromycin (type 3) with *Nocardia nova* (Wallace et al., 1991). Members of these species contain serious pathogens (Farina et al., 2007; Poonwan et al., 2005; Schaal and Lee, 1992). Indeed, the high mortality associated with disseminated *Nocardia farcinica* infections in immunosuppressed patients may be compounded by the resistance of some strains to multiple antimicrobial agents (Hitti and Wolff, 2005; Torres et al., 2000). The antibiotic sensitivity profiles of individual *Nocardia* species are given in the species descriptions.

Pathogenicity. *Nocardia* species are being isolated with increasing frequency from clinical material, especially from specimens taken from immunocompromised patients (Boiron et al., 1998; Farina et al., 2001; Poonwan et al., 2005; Saubolle and Sussland, 2003; Serrano et al., 2007). The best known nocardial pathogens are agents of suppurative and granulomatous diseases in humans and animals, notably mycetoma and nocardiosis (Beaman and Beaman, 1994; Boiron et al., 1993; Brown-Elliott et al., 2006; Goodfellow, 1998; McNeil and Brown, 1994).

Mycetoma, a localized chronic, granulomatous, progressive inflammatory disease that involves subcutaneous tissue and sometimes bone (Brown-Elliott et al., 2006; Fahal, 2004; Fahal, 2006; Schaal and Beaman, 1984), is endemic in certain tropical and subtropical regions where it has a devastating effect on patients (and rural communities) as it often leads to deformities and amputations with a consequent loss of their livelihood. Characteristic features of the disease are one or more painless subcutaneous masses of inflammatory cells and sinus tracts, which may discharge granules (small colonies) of the infective agent. The disease process usually begins at the site of a localized injury, such as puncture wounds caused by thorns or splinters.

Mycetoma may be caused by fungi (eumycetes) or by aerobic, filamentous actinomycetes and hence is classified into eumycetoma and actinomycetoma, respectively. Approximately 60% of mycetoma cases worldwide are caused by actinomycetes, the rest by fungi (Vera-Cabrera et al., 2004). *Nocardia asteroides, Nocardia brasiliensis, Nocardia otitidiscaviarum*, and *Nocardia transvalensis*, and more recently recognized species such as *Nocardia abscessus, Nocardia africana, Nocardia mexicana*, and *Nocardia veterana*, have been reported to cause human mycetoma (Beaman and Beaman, 1994; Buot et al., 1987; Fahal, 2006; Horre et al., 2002; Kano et al., 2002; Lum and Vadmal, 2003; Mirza and Campbell, 1994). The major causal agent remains *Nocardia brasiliensis*; this

organism is responsible for the vast majority of mycetoma cases in Mexico (Lopez Martinez et al., 1992) though other *Nocardia* species, such as *Nocardia mexicana*, may be overlooked since the identification of *Nocardia brasiliensis* strains is often based on a small number of phenotypic properties (Rodriguez-Nava et al., 2004). Mycetoma has been simulated in a mouse model (González-Ochoa, 1973; Salinas-Carmona et al., 1999; Zlotnik, 2007; Zlotnik and Buckley, 1980), which has been used to study host–parasite relationships (Ortiz-Ortiz et al., 1984).

In contrast to actinomycetoma, nocardiosis has a worldwide distribution. It usually develops as an opportunistic or disseminated infection which complicates primary diseases, such as leukemia, lymphoma, and other neoplasms (Brown-Elliott et al., 2006; McNeil and Brown, 1994). Other predisposing factors include immunosuppressive treatments, particularly steroid therapy, chronic bronchopulmonary disease, organ transplantations, and acquired immunodeficiency syndrome (Choucino et al., 1996; Diego et al., 2005; Gallant and Ko, 1996; Patel and Paya, 1997). However, in immunocompetent hosts, infection usually appears after traumatic inoculation into the skin and remains localized (Beaman and Beaman, 1994; Maraki et al., 2004). Nocardia–host interactions have been studied using mice as the experimental animal (Beaman, 1973, 1992, 1993; Beaman and Ogata, 1993; Beaman and Beaman, 1993).

Accurate diagnosis and treatment of actinomycetoma and nocardiosis depend upon the isolation and identification of the causal organisms (Brown-Elliott et al., 2006; Goodfellow, 1998; McNeil and Brown, 1994). The procedures involved are laborious and somewhat cumbersome hence the true incidences of these diseases are underestimated, a problem sometimes compounded by poor documentation and misidentification of the causal agents. The recent dramatic increases in the reported frequency of human nocardial infections can be attributed to the widespread use of immunosuppressive drugs, improved selective isolation procedures, and raised clinical and microbiological awareness (Brown-Elliott et al., 2006; Goodfellow, 1998; Poonwan et al., 2005). However, in countries where chronic lung diseases (particularly tuberculosis) are prevalent, nocardiosis cases may be missed (Baily et al., 1988; Idigbe et al., 1999; Koffi et al., 1998; McLeod et al., 1989; Osoagbaka, 1984; Osoagbaka and Njoku-Obi, 1985). This situation is unsatisfactory as identification of clinically significant nocardiae to the species level is needed to determine the spectrum of diseases caused by members of individual *Nocardia* species and for predicting effective antimicrobial therapy (Brown-Elliott et al., 2006; Conville et al., 2000; Hamid et al., 2001b).

Human cases of nocardiosis can be distinguished clinically as skin infections (cutaneous, subcutaneous, and lymphocutaneous), pulmonary and extrapulmonary nocardioses, and systemic infections which involve two or more body sites (Schaal, 1998; Schaal and Beaman, 1984). In general, cutaneous and lymphocutaneous nocardioses are caused by *Nocardia asteroides, Nocardia brasiliensis*, and *Nocardia otitidiscaviarum*, and sporadically by *Nocardia farcinica* and *Nocardia transvalensis*. Most pulmonary and systemic infections in temperate regions are due to *Nocardia asteroides, Nocardia brasiliensis, Nocardia farcinica*, and *Nocardia nova*, and fewer to *Nocardia brasiliensis, Nocardia otitidiscaviarum, Nocardia pseudobrasiliensis*, and *Nocardia transvalensis* (Farina et al., 2001, 2007; Palmer et al., 1974; Pottumarthy et al., 2003; Torres et al., 2000).

Additional agents of pulmonary nocardiosis include *Nocardia africana*, an organism described by Hamid et al. (2001b) for strains isolated from sputum of patients with chronic pulmonary infections, and *Nocardia veterina* (Conville et al., 2003; Pottumarthy et al., 2003). The most prevalent agents of nocardiosis in Thailand were reported to be *Nocardia beijingensis, Nocardia cyriacigeorgica*, and *Nocardia farcinica* (Poonwan et al., 2005). *Nocardia farcinica*, in particular, is a serious and versatile pathogen which is known to cause cerebral, cutaneous, and pulmonary abscesses (Farina et al., 2007; Hitti and Wolff, 2005; Kageyama et al., 2001; Schaal and Lee, 1992). Other strains isolated from abscesses have been described as *Nocardia abscessus* (Yassin et al., 2001b), *Nocardia niigatensis* (Kageyama et al., 2004i), *Nocardia nova* (Hamdad et al., 2007), *Nocardia puris* (Yassin et al., 2003), and *Nocardia yamanashiensis* (Kageyama et al., 2004i). *Nocardia abscessus* has been reported as the cause of disseminated nocardiosis in an HIV patient (Diego et al., 2005).

At one time, nocardiosis was considered to be a late presenting, community acquired infection but it is now known that the disease is transmissible (Cox and Hughes, 1975; Exmelin et al., 1996; Young et al., 1971). Clusters of patients with *Nocardia asteroides* infections have been reported from liver (Sahathevan et al., 1991) and renal transplant units (Baddour et al., 1986; Houang et al., 1980; Palmer et al., 1974). Schaal (1991) considered that nosocomial airborne transmission, possibly in the operating room environment, was responsible for a cluster of *Nocardia farcinica* postoperative wound infections in patients undergoing cardiac and other vascular surgeries at a university hospital. The isolation of immunosuppressed patients from ones with nocardiosis has been recommended (Houang et al., 1980; Stevens et al., 1981). Nocardial infections also occur in HIV patients (Javaly et al., 1992; Kim et al., 1991; Poonwan et al., 1995).

Blaine Beaman and his colleagues have carried out extensive studies on the mechanisms involved in pathogenicity as well as on host immunity to nocardial infections (Beaman and Beaman, 1992, 1993, 1994, 1998, 2000; Beaman and Moring, 1988). They showed that virulent strains of *Nocardia asteroides* were facultative intracellular pathogens that grew in a variety of cells from humans and experimental animals. The virulence of *Nocardia asteroides* appears to be associated with several factors, such as the stage of the growth cycle, its ability to inhibit phagosome–lysozyme fusion, neutralize phagosomal acidification, resist oxidative killing mechanisms of phagocytes, alter lysosomal enzymes within phagocytes, and invade and grow within the brains of experimental animals. However, the mechanisms of host resistance to nocardial infections are complex and poorly understood (Beaman, 1992) and the role of L forms in nocardial infections is not known (Beaman, 1982).

Nocardiae cause infections in animals (Beaman and Beaman, 1994; Beaman and Sugar, 1983; Ramos-Vara et al., 2007). Animals susceptible to nocardial infections include antelopes, armadillos, birds, cats, cattle, chickens, deer, dogs, dolphins, ducks, fish, foxes, goats, guinea pigs, horses, orangutans, sheep, and whales. The most frequently recognized conditions are systemic and pulmonary nocardioses, including infections of the brain. In dairy animals, notably cows, nocardial mastitis can be a major problem (Battig et al., 1990; Bushnell et al., 1979; Da Costa et al., 1996; Manninen et al., 1993; Stark and Anderson, 1990); strains involved in an epizootic in Canada

were provisionally classified as *Nocardia farcinica* (Manninen et al., 1993). This organism has been shown to be a significant cause of mastitis in goats in the Sudan (Maldonado et al., 2004). The most frequently recognized nocardial pathogens of animals are *Nocardia asteroides, Nocardia brasiliensis*, and *Nocardia otitidiscaviarum. Nocardia crassostreae* causes nocardioses in Pacific oysters (Friedman et al., 1998); *Nocardia salmonicida* and *Nocardia seriolae* are fish pathogens (Isik et al., 1999b; Kudo et al., 1988; Rucker, 1949). *Nocardia africana* has been isolated from a feline mycetoma (Hattori et al., 2003).

Ecology. Nocardiae are widely distributed in aquatic and terrestrial habitats and form mutualistic associations with blood-sucking arthropods (Cross et al., 1976; Goodfellow and Williams, 1983; Xu et al., 1996; Yamamura et al., 2003b), though they are known best as causal agents of mycetoma and nocardiosis (Brown-Elliott et al., 2006; McNeil and Brown, 1994). However, their primary habitat is probably soil as populations of up to 1.4×10^5 colony forming units per gram dry weight have been reported from diverse temperate and tropical soils (Orchard et al., 1977; Xu et al., 1996). Large nocardial populations have been reported from sediment and water samples collected from lakes in Yunnan Province, South-west China (Jiang and Xu, 1996; Jiang and Xu, 1985), from soil amended with municipal water, sewage effluent, or dried sludge derived from domestic and industrial sources (Orchard, 1978, 1979, 1981), and from oil contaminated soil (Khan et al., 1997).

The lack of knowledge about the functional activities of nocardiae in natural habitats is lamentable though some evidence shows that they have a role in the turnover of organic matter (Goodfellow and Williams, 1983; Orchard, 1979, 1981). They have been implicated in the biodeterioration of natural rubber joints in water and sewage pipes (Hookey, 1984; Hutchinson et al., 1975) and in the formation of foam in activated sludge plants (Seviour and Nielsen, 2010; Soddell and Seviour, 1990). Indeed, nocardiae have been considered to be the major causal agents of foaming (Jenkins et al., 1993), but it is now evident that diverse mycolic acid-containing taxa are involved, notably members of the genera *Gordonia, Skermania*, and *Tsukamurella* (Blackall et al., 1989; Chun et al., 1997; Goodfellow et al., 1996; Soddell et al., 1992; Soddell and Seviour, 1998; Stainsby et al., 2002).

Improvements in the classification of the genus *Nocardia* provide a sound framework for the circumscription of new species isolated from man-made and natural habitats. Novel taxa isolated from terrestrial habitats include *Nocardia amamiensis* from a sugar-cane field (Yamamura et al., 2007), *Nocardia cerradoensis* from a Cerrado soil (Alburquerque de Barros et al., 2003), *Nocardia coubleae* from oil-contaminated soil (Rodriguez-Nava et al., 2007), *Nocardia jiangxiensis* from an acid pine forest soil (Cui et al., 2005), and *Nocardia neocaledoniensis* from a brown hypermagnesian ultramafic soil (Saintpierre-Bonaccio et al., 2004). Similarly, *Nocardia harenae* was isolated from beach sand (Seo and Lee, 2006), *Nocardia jejuensis* and *Nocardia speluncae* from a natural cave (Lee, 2006; Seo et al., 2007), and *Nocardia takedensis* from scumming activated sludge (Yamamura et al., 2005). Such studies are important as they provide a basis for determining the distribution and activities of individual *Nocardia* species in the environment. *Nocardia pseudovaccinii* was proposed to accommodate two strains previously assigned to the plant pathogen *Nocardia vaccinii* (Kim et al., 2002b).

Isolation procedures

Traditional isolation procedures were based on the ability of nocardiae to metabolize hydrocarbons as sole sources of carbon and energy for growth (Cross et al., 1976; Nesterenko et al., 1978a; Tárnok, 1976). Modifications of Söhngen's paraffin baiting technique (Sőhngen, 1913) have been used to isolate nocardiae from clinical specimens and soil (Ashdown, 1990; Khan et al., 1997; Ollar, 1976; Portaels, 1976; Schaal and Bickenbach, 1978), but they merely indicate the presence or absence of the organisms without providing any quantitative data. Similarly, alternative isolation methods, such as inoculating hamster or guinea pig testicles with soil suspensions supplemented with penicillin and streptomycin (Conti-Diaz et al., 1971), or plating suspensions onto media which contain cholesterol acetate and sodium azide (Farmer, 1962), underestimate nocardial populations in natural habitats.

It is now common practice to isolate *Nocardia* strains from pretreated or non-pretreated clinical or environmental samples followed by plating serial dilutions onto either general purpose or selective media supplemented with antifungal antibiotics (e.g., actidione and nystatin at 50 μg/ml). Inoculated media are incubated at 25, 30, or 37°C for up to 3 weeks followed by colony selection and characterization. It is surprising given the biotechnological, clinical, and ecological importance of nocardiae that an agreed, effective selective isolation procedure is not available. However, large numbers of nocardiae have been isolated by plating heat pretreated soil suspensions (55°C for 6 min) onto Diagnostic Sensitivity Test (DST) agar supplemented with antifungal antibiotics and various combinations of tetracycline antibiotics (Orchard and Goodfellow, 1974; Orchard et al., 1977). Characteristic colonies with pink to red substrate mycelium and sparse to abundant white aerial hyphae are evident following incubation at 25°C for up to 3 weeks. Such colonies have been provisionally classified as *Nocardia asteroides* (Orchard and Goodfellow, 1974; Orchard et al., 1977) though *Nocardia cummidelens, Nocardia fluminea*, and *Nocardia soli* have been isolated from soil and water samples (Maldonado et al., 2000). It seems likely that at least some strains of *Nocardia asteroides* will be inhibited by the antibacterial antibiotics in DST agar (Schaal and Heimerzhein, 1974). A selective medium free of such antibiotics has been used to isolate *Nocardia asteroides* from clinical material (Schaal, 1972).

Small numbers of nocardiae have been isolated from soil on nutrient rich media, as exemplified by the isolation of *Nocardia alba* and *Nocardia lijianensis* on HV agar (Li et al., 2004a; Xu et al., 2005), *Nocardia beijingensis* on glucose-asparagine agar (Wang et al., 2001), *Nocardia caishjiensis* on Bennett's agar (Zhang et al., 2003), *Nocardia cerradoensis* on R5 agar (Alburquerque de Barros et al., 2003), *Nocardia neocaledoniensis* on oatmeal agar (Saintpierre-Bonaccio et al., 2004), *Nocardia polyresistens* on proline-tap water agar (Xu et al., 2005), *Nocardia tenerifensis* on soil extract agar (Kämpfer et al., 2004), and *Nocardia xishanensis* on modified Sauton's agar (Zhang et al., 2004). *Nocardia amamiensis* was isolated from soil using the SDS/yeast extract pretreatment method (Hayakawa and Nonomura, 1989) and HV agar supplemented with nalidixic acid (Yamamura et al., 2007), and *Nocardia jiangensis* and *Nocardia miyunensis* by plating soil suspensions, prepared using the dispersion and differential centrifugation procedure (Wang et al., 2003), onto acidified selective isolation medium (Cui et al., 2005). Large numbers

of nocardiae have been isolated by spreading dilutions of sediment, soil, and water samples onto rich media, such as colloidal chitin agar, glycerol-asparagine agar, and starch-casein agar (Jiang and Xu, 1996; Xu et al., 1996).

Nonselective media such as brain heart infusion and Sabouraud's glucose agars have been recommended for the isolation of clinically significant nocardiae (Schaal, 1977). Sabouraud's glucose agar supplemented with chloramphenicol has been used to recover nocardiae from sputum (Ajello and Roberts, 1981) though many nocardiae are inhibited by this antibiotic (Gutmann et al., 1983). Similarly, decontamination of respiratory specimens using procedures applied to the isolation of mycobacteria have been shown to kill nocardiae (Murray et al., 1987). However, Hamid et al. (2001b) isolated *Nocardia africana* strains on Lowenstein-Jensen slopes which had been inoculated with sputum samples taken from patients with pulmonary disease then treated using the digestion-decontamination technique of Roberts et al. (1991); most of the patients had either failed to respond to anti-tubercular drug treatment or had responded then relapsed. The use of chemically defined media containing paraffin agar may prove to be an effective way of selectively isolating nocardiae from clinical specimens (Shawar et al., 1990).

Specific *Nocardia* species have been isolated from clinical material using rich nutrient media, as illustrated by the isolation of *Nocardia araoensis* on Ogawa agar (Kageyama et al., 2004g) and *Nocardia ignorata* from brain heart infusion agar (Yassin et al., 2001b). *Nocardia asteroides* and *Nocardia otitidiscaviarum* have been isolated by plating foam from activated sludge plants onto either Czapek's agar supplemented with yeast extract (Higgins and Lechevalier, 1969) or glycerol agar (Gordon and Smith, 1953) and incubating plates for 5–7 d at 28°C. *Nocardia takedensis* was isolated from scumming activated sludge using a *Nocardia* isolation method based on sucrose-gradient centrifugation (Yamamura et al., 2003a, 2005). Stratton et al. (1996) isolated strains using a micromanipulator to pick up cocco-bacillary elements prior to plating them onto R2A agar.

Maintenance procedures

A convenient method for short-term storage involves serial transfer every 2 months from appropriate media, such as modified Bennett's (Jones, 1949) and glucose-yeast extract agar slopes (Gordon and Mihm, 1962) with storage between transfers at 4°C. Long-term preservation can be achieved by lyophilization, storage in liquid nitrogen, or by using frozen glycerol suspensions. For lyophilization, biomass is suspended in a suitable fluid such as glucose serum (7.5%, w/v) or skimmed milk supplemented with glucose (7.5%, w/v). For preservation in liquid nitrogen, biomass is inoculated into a suitable medium held in small tubes until sufficient growth is visible. Such preparations are sealed with cotton wool plugs dipped in liquid paraffin wax and placed in a liquid nitrogen container. Glycerol suspensions are prepared by scraping growth from heavily inoculated agar plates and making heavy suspensions in aqueous glycerol (3 ml) held in small vials which are stored at −20°C (Wellington and Williams, 1978).

Differentiation of the genus *Nocardia* from other genera

The genus *Nocardia* can be difficult to distinguish from other mycolic acid-containing taxa and from other filamentous actinomycetes using standard staining and morphological properties. *Nocardia* strains that lack aerial hyphae, for instance, can be difficult to distinguish from mycobacteria, rhodococci, and "bald" streptomycetes whereas those with abundant aerial hyphae can be confused with genera classified in the families *Pseudonocardiaceae, Streptosporangiaceae*, and *Thermomonosporaceae*. Until recently, reliable differentiation of mycolic acid-containing genera depended on the use of a combination of morphological and chemical markers (see Table 29 in the *Corynebacteriales* chapter).

Simplified procedures are available for the detection of staining and morphological properties (Goodfellow, 1996), cell wall constituents (Hancock, 1994), including the acyl type of muramic acid (Uchida et al., 1999), fatty acids (McNabb et al., 1997; Suzuki et al., 1993), and mycolic acids (Butler et al., 1986; Embley and Wait, 1994; Nishiuchi et al., 2000), menaquinones (Collins et al., 1985), and polar lipids (Suzuki et al., 1993). Such procedures are being complemented, and to some extent replaced, by molecular systematic methods (Gürtler and Mayall, 2001), notably by 16S rRNA gene sequencing studies (Stackebrandt et al., 1997; Zhi et al., 2009). The methods used to distinguish mycolic acid-containing genera from one another and from other filamentous actinomycete taxa are considered in greater detail in the section on the order *Corynebacteriales*.

Taxonomic comments

The long and intricate taxonomic history of the genus has been the subject of several comprehensive reviews (Goodfellow, 1992, 1996; Goodfellow et al., 1998a, 1999; Goodfellow and Minnikin, 1977; Lechevalier, 1976; Minnikin and Goodfellow, 1980) and hence will not be considered in detail here. The genus was proposed by Trevisan (1889) to accommodate five species, one of which *Nocardia farcinica*, contained an aerobic filamentous organism which Edmond Nocard had isolated in Guadeloupe in 1888 from lesions in cattle suffering from farcy. *Nocardia farcinica*, which, because it was cited first, was subsequently assumed to be the type species while a second species, *Nocardia foersteri*, was the first actinomycete to be described (Cohn, 1875). One year later, in 1896, Eppinger isolated an aerobic, branching filamentous organism from a human with a fatal brain abscess and named it *Cladothrix asteroides*, but soon thereafter it was renamed *Nocardia asteroides* Blanchard 1896. Early additions to the genus *Nocardia* included several agents of disease, namely *Nocardia asteroides* (Eppinger 1891) Blanchard 1896, *Nocardia brasiliensis* (Lindenberg 1909) Pinoy 1913, *Nocardia otitidiscaviarum* corrig. Snijders 1924, and *Nocardia transvalensis* Pijper and Pullinger 1927. Subsequently, the genus became a dumping ground for a heterogeneous assortment of nocardioform actinomycetes, i.e., strains grouped around *Nocardia*, which were considered to form a mycelium that fragmented into coccoid and rod-like elements (see Lechevalier, 1976).

It was only with the application of new taxonomic methods, notably chemotaxonomy, molecular systematics and numerical phenetic taxonomy, that dramatic improvements were made in the classification of nocardioform actinomycetes. Species previously assigned to the genus *Nocardia* were classified directly or indirectly into either established or novel mycolic acid-containing genera (*Gordonia, Rhodococcus*, and *Skermania*) or into corresponding taxa that lacked mycolic acids (*Actinomadura, Amycolatopsis, Cellulomonas, Lechevalieria, Nocardiopsis, Oerskovia, Prauserella, Pseudonocardia*, and *Rothia*). The redefined

genus contained only 9 of the 20 species listed under *Nocardia* in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), namely *Nocardia amarae, Nocardia asteroides, Nocardia brasiliensis, Nocardia brevicatena, Nocardia carnea, Nocardia farcinica, Nocardia otitidiscaviarum, Nocardia transvalensis,* and *Nocardia vaccinii.*

Gordon and her colleagues brought considerable clarity into the taxonomy of the species *Nocardia asteroides, Nocardia brasiliensis, Nocardia carnea, Nocardia otitidiscaviarium, Nocardia transvalensis,* and *Nocardia vaccinii* based on pioneering studies in which they used a broad range of phenotypic properties (Gordon and Mihm, 1957, 1959, 1962a, 1962b; Gordon et al., 1978; Mishra et al., 1980). Data summarized from these publications together with corresponding results from studies on *Nocardia amarae* and *Nocardia brevicatena* (Goodfellow et al., 1982b, 1982c; Goodfellow and Pirouz, 1982a; Lechevalier, 1968; Lechevalier and Lechevalier, 1974) featured prominently in the section on *Nocardia* in the last edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow and Lechevalier, 1989).

Goodfellow and his coworkers considered *Nocardia amarae, Nocardia brasiliensis, Nocardia farcinica,* and *Nocardia otitidiscaviarum* to be sound taxospecies, but, like other workers, stressed that *Nocardia asteroides*, as defined by Gordon, was markedly heterogeneous (Bradley et al., 1978; Goodfellow, 1971; Kurup et al., 1983; Kurup and Scribner, 1981; Magnusson, 1976; Mordarski et al., 1977, 1978; Pier and Fichtner, 1971, 1981; Ridell, 1981; Schaal and Reutersberg, 1978; Tsukamura, 1977). The subsequent recognition of *Gordonia amarae* (Lechevalier and Lechevalier 1974) Klatte et al. 1994b for actinomycetes previously classified as nocardiae was a key development in nocardial systematics as the genus *Nocardia* was left as a well-delineated taxon for the first time since its inception. The remaining *Nocardia* species cited on the *Approved Lists of Bacterial Names* (Skerman et al., 1980) were assigned to several established and novel genera as outlined in the *Nocardia* chapter in the last edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow and Lechevalier, 1989).

The principal nomenclatural problem in the redescribed genus *Nocardia* was the status of the original type species, *Nocardia farcinica.* The strain, originally isolated by Nocard (1888) from a case of bovine farcy was, by the decision of the Judicial Commission in 1954, made the type species of the genus *Nocardia.* It subsequently became known that Nocard's original isolate was represented by two supposedly identical, but actually very different strains, ATCC 3318 and NCTC 4524. The former contained mycolic acids characteristic of nocardiae, and the latter mycolic acids and mycosides similar to those of mycobacteria (Lanéelle et al., 1971; Lechevalier et al., 1971). Orchard and Goodfellow (1980) found that these strains fell into different clusters defined in their numerical taxonomic study. Schaal and Reutersberg (1978) found that ATCC 3318 clustered with *Nocardia asteroides* strains, but they did not examine NCTC 4524. Using serological and physiological data, Ridell (1975) noted that the latter strain grouped with mycobacteria and ATCC 3318 with *Nocardia asteroides,* thereby confirming her previous results using immunodiffusion; the latter showed that some *Nocardia farcinica* strains were closer to mycobacteria than to nocardiae (Ridell and Norlin, 1973). Base composition studies also showed that strains ATCC 3318 and NCTC 4524 were different, the mol% G+C values being 68.0 and 71.6, respectively (Mordarski et al., 1978), as did phage sensitivity studies (Prauser, 1981b). In view of the uncertain status of *Nocardia farcinica* (Lechevalier, 1976), the type species of the genus was changed to *Nocardia asteroides,* with ATCC 19247 as the type strain (Judicial Commission of the International Committee on Systematic Bacteriology, 1985; Skerman et al., 1980; Sneath, 1982) and *Nocardia farcinica* retained, with ATCC 3318 as the type. An appeal to the Judicial Commission to reject *Nocardia farcinica* as a *nomen dubium* was published (Tsukamura, 1982a); however, the commission voted to retain the *farcinica* epithet.

The improved classification of the genus has provided a sound framework for the recognition of novel pathogenic *Nocardia* species and for the reclassification of misclassified strains (Goodfellow et al., 1999). Species encompassing human and animal pathogens, such as *Nocardia brasiliensis, Nocardia crassrostreae,* and *Nocardia otitidiscaviarum,* were considered to be homogeneous whereas others, notably *Nocardia asteroides,* were seen to be heterogeneous. *Nocardia asteroides* contained a mish mash of strains which included *Nocardia asteroides sensu stricto, Nocardia farcinica,* and *Nocardia nova* (Tsukamura, 1982a; Wallace et al., 1991; Yano et al., 1990) and several biotypes and serotypes (Kurup et al., 1983; Kurup and Scribner, 1981; Wallace et al., 1988, 1990). However, regardless of their designation, members of what became known as the *Nocardia asteroides* complex have been frequently isolated from humans and animals with serious, often fatal, infections (Beaman and Sugar, 1983; Wallace et al., 1990, 1991).

The confusion over the taxonomic status of *Nocardia asteroides* and related strains led to additional clinically significant isolates being assigned to the *Nocardia asteroides* complex (Ambaye et al., 1997; Poonwan et al., 1995), a practice which has continued until quite recently (Farina et al., 2001; Pintado et al., 2002; Saubolle and Sussland, 2003). This situation is unsatisfactory as rapid and accurate identification of clinically significant nocardiae to the species level is at a premium for predicting antimicrobial susceptibilities, especially given the potential of nocardiae to cause infections in the growing immunocompromised patient community (Patel et al., 2004; Wauters et al., 2005). It is also unfortunate that the type strain of *Nocardia asteroides* does not represent any of the common nocardiae associated with clinical nocardiosis (Baba et al., 1997; Patel et al., 2004).

Additional improvements in nocardial systematics (Goodfellow and Maldonado, 2006) have clarified relationships between isolates assigned to the *Nocardia asteroides* complex, as exemplified by the recognition of several new species, such as *Nocardia abscessus* (Yassin et al., 2000b), *Nocardia anemiae* (Kageyama et al., 2005d), *Nocardia araoensis* (Kageyama et al., 2004g), *Nocardia cyriacigeorgica* (Yassin et al., 2001a), and *Nocardia higoensis* (Kageyama et al., 2004f). Similarly, isolates assigned to the *Nocardia transvalensis* 16S rRNA gene clade have been given species status as *Nocardia blacklockiae* and *Nocardia wallacei* (Conville et al., 2008, 2009), and strains misclassified as *Nocardia brasiliensis* have been assigned to two species, *Nocardia mexicana* (Rodriguez-Nava et al., 2004; Rodriguez-Nava, 2006) and *Nocardia pseudobrasiliensis* (Ruimy et al., 1996). Additional new species of human origin include *Nocardia asiatica* (Kageyama et al., 2004b), *Nocardia kruczakiae* (Conville et al., 2004, 2005), and *Nocardia testaceae* corrig Kageyama et al. (2004h).

The improved procedures available for the circumscription of *Nocardia* species have led to the recognition of new species

isolated from natural habitats, including *Nocardia acidovorans* (Kämpfer et al., 2007), *Nocardia alba* (Li et al., 2004b), *Nocardia amamiensis* (Yamamura et al., 2007), *Nocardia coubleae* (Rodriguez-Nava et al., 2007), *Nocardia lijianensis* (Xu et al., 2006b), *Nocardia neocaledoniensis* (Saintpierre-Bonaccio et al., 2004), and *Nocardia xishanensis* (Zhang et al., 2004). In addition, strains assigned to the *Nocardia vaccinii* 16S rRNA gene clade have been reclassified as two new species, *Nocardia elegans* (Yassin and Brenner, 2005) and *Nocardia pseudovaccinii* (Kim et al., 2002b).

The genus *Nocardia* encompasses 75 validly published species the majority of which have been delineated using a broad range of genotypic and phenotypic properties, including DNA–DNA relatedness data. However, despite the recent explosion in the number of *Nocardia* species, the genus is still underspeciated (Liu et al., 1983; Maldonado et al., 2000; Orchard and Goodfellow, 1980; Patel et al., 2004; Roth et al., 2003; Wang et al., 1999). It also seems likely that strains assigned to the *Nocardia asteroides* complex will be found to merit recognition as new species (Goodfellow et al., 1999; Roth et al., 2003). The type strain of *Nocardia asteroides* forms a distinct phyletic line in the 16S rRNA *Nocardia* gene tree and can be readily distinguished from most other pathogenic nocardiae based on numerical phenotypic data (Goodfellow et al., 1999) and on the composition of mycolic acid molecular species determined by gas-chromatography-mass spectrometry (Baba et al., 1997).

Differentiation of the species *Nocardia*

Nocardia species remain difficult to identify even though a multiplicity of diagnostic procedures have been recommended for this purpose (Baba et al., 1997; Boiron et al., 1993). Nevertheless, in practice, unknown nocardiae can be assigned to established or novel species by first establishing their position in the 16S rRNA gene tree (Figure 88) followed, where necessary, by DNA–DNA relatedness studies and finally by the application of biochemical, degradation and nutritional tests (Table 39). This approach is simple in theory but in practice it is beset by difficulties, not only because the time taken from the acquisition of specimens to identification can take several weeks but also because the process is labor intensive. These problems are compounded by the lack of an agreed set of diagnostic phenotypic tests and by the fact that the latter can give unreliable data, especially since many recently proposed *Nocardia* species are based on descriptions of single strains. To compensate for such problems, supplementary tests grounded on antibiotic sensitivity and enzyme activity have been recommended for the delineation of some *Nocardia* species (Biehle et al., 1996; Boiron and Provost, 1988a, 1988b, 1990b, 1990c; Boiron et al., 1993; Wilson et al., 1998), as has the use of carbon utilization profiles (Kämpfer et al., 2004, 2007; Kim et al., 2002b). An abbreviated set of phenotypic tests have been proposed for the identification of medically significant nocardiae (Kiska et al., 2002). In addition, laboratory specialists need to be aware of the occasional occurrence of unusual strains of *Nocardia asteroides* (Boiron et al., 1990).

The difficulties associated with the identification of *Nocardia* species using phenotypic tests led to the introduction of a plethora of molecular-based procedures, particularly for the identification of clinically significant nocardiae. The application of 16S rRNA gene sequencing was instrumental in the delineation of numerous new *Nocardia* species and, as noted earlier, many of these were clinically significant. Methods specifically developed for the identification of clinically significant nocardiae included the polymerase chain reaction (PCR) coupled with restriction endonuclease analysis of PCR products (Isik et al., 2002; Rodriguez-Nava et al., 2006; Steingrübe et al., 1995, 1997; Wilson et al., 1998), PCR-randomly amplified polymorphic DNA fingerprinting (Isik et al., 2002), partial 16S rRNA gene sequencing (Cloud et al., 2004; Patel et al., 2004), and sequence analysis of a portion of the *secA1* gene (Conville et al., 2006). However, when using sequence-based identification procedures it is important to be aware of potential complications which may be caused by the presence of differing 16S rRNA genes in the same isolates (Conville and Witebsky, 2005). DNA probes have been developed for the identification of *Nocardia asteroides* using genomic based libraries generated from selected members of the species (Brownell and Belcher, 1990), and a digoxigenen-labeled cDNA library for the recognition of *Nocardia farcinica* (McNeil et al., 1997).

The long-term practical value of diagnostic molecular approaches to the identification of pathogenic nocardiae, such as those outlined above, is difficult to forsee due to the need to apply them to the expanding number of pathogenic *Nocardia* species (Conville et al., 2006). This problem is exacerbated by the discovery that key pathogenic species, such as *Nocardia farcinica, Nocardia nova, Nocardia otitidiscaviarum*, and *Nocardia transvalensis*, are heterogeneous (Baba et al., 1997; Patel et al., 2004)—an observation that is a timely reminder of the need to build reliable identification procedures on sound classifications (Goodfellow, 2000). However, direct molecular diagnosis of nocardiosis has proved decisive in culture-negative cases of the disease (Couble et al., 2005; Marchandin et al., 2006).

Serological procedures and skin testing for cutaneous hypersensitivity were applied for many years for the early diagnosis of nocardial infections in animals and humans (Boiron et al., 1993; Bojalil and Zamora, 1963; Ortiz-Ortiz et al., 1976; Pier, 1984; Shainhouse et al., 1978). An enzyme-linked immunosorbent assay (ELISA) technique based on a 55-kDa protein specific for *Nocardia* allowed the detection of antibodies in over 90% of patients afflicted with either cutaneous or pulmonary nocardiosis (Angeles and Sugar, 1987). Similarly, a conventional solid-phase ELISA, based on two immunodominant antigens, was used for the diagnosis of *Nocardia brasiliensis* infections in mycetoma patients (Salinas-Carmona et al., 1993) and a partially purified 54-kDa antigen introduced for the diagnosis of nocardiosis using an immunoblot technique (Boiron and Provost, 1990a; Boiron and Stynen, 1992). Polysaccharide antigens, extracted and purified from *Nocardia asteroides* and *Nocardia brasiliensis* cells, have been used to test for cutaneous hypersensitivity (Zamora et al., 1963). Antigens in culture filtrates have been employed to detect the distribution of *Nocardia asteroides* serotypes (Pier and Fichtner, 1971, 1981) and to determine cutaneous hypersensitivity in animals and humans infected with *Nocardia asteroides, Nocardia brasiliensis*, and *Nocardia otitidiscaviarum* (Pier et al., 1968; Salman et al., 1982). In recent times, serological procedures have fallen out of favor, partly because of their low sensitivity and lack of specificity, partly because of the popularity of diagnostic molecular procedures, but also because of the limited value of individual serological techniques in detecting nocardial diseases which are now known to be caused by members of several *Nocardia* species.

Reliable typing methods are needed to establish the infection source and mode of transmission of clinically significant nocardiae, notably with respect to hospital acquired infections (Brown-Elliott et al., 2006; McNeil and Brown, 1994; Schaal and Lee, 1992). Serological typing of *Nocardia asteroides* is a useful epidemiological tool, as shown by investigations on group infections. Studies on herds of dairy cattle where cases of mastitis were evident showed that the infecting causal agents were usually of the same serotype implying animal-to-animal transmission (Pier and Fichtner, 1981). Similarly, an outbreak of nocardiosis in immunocompromised patients in a renal unit was attributed to a specific *Nocardia asteroides* serotype (Stevens et al., 1981). All of the strains isolated from the environment of the renal unit were of the same serotype whereas corresponding serotypes from different areas of the hospital and from nocardiosis patients from other hospitals were a more random mix. These results were indicative of a patient-to-environment-to patient cycle of infection in the renal unit.

Nocardia asteroides strains have been typed using plasmid (Jonsson et al., 1986) and restriction fragment length polymorphism (RFLP; Patterson et al., 1992) profiles. These latter workers showed that 18 out of 19 clinical isolates shared an identical RFLP pattern using the restriction enzyme *Pvu*III. Pulsed field gel electrophoresis has been used to distinguish between *Nocardia asteroides* strains implicated in a suspected outbreak of nocardiosis (Louie et al., 1997). This technique was used to show that a *Nocardia farcinica* strain was responsible for postoperative wound infections in a hospital surgical ward in Germany (Blümel et al., 1998). These investigators found that organisms with the same genotype were present in air samples taken from the same location and were the causal agents of additional pulmonary infections in an area close to the surgical ward.

List of species of the genus *Nocardia*

1. **Nocardia asteroides** (Eppinger 1891) Blanchard 1896, 856 (Approved Lists 1980) ("*Cladothrix asteroides*" Eppinger 1891: "*Streptothrix eppingerii*" (*sic*) Rossi-Doria 1891; "*Streptothrix asteroids*" (*sic*) (Eppinger 1891) Gasperini 1892): "*Oospora asteroides*" (Eppinger 1891) Sauvageau and Radais 1892; "*Actinomyces asteroides*" (Eppinger 1891) Gasperini 1894; "*Actinomyces eppingeri*" (Rossi-Doria 1891) Berestnev 1897; *Discomyces asteroides* (Eppinger 1891) Gedoelst 1902; "*Actinomyces eppinger*" (*sic*) (Rossi-Doria 1891) Namyslowski 1912; "*Asteroides asteroides*" (Eppinger 1891) Puntoni and Leonardi 1936; "*Proactinomyces asteroids*" (Eppinger 1891) Baldacci 1937.

as′te.ro′i.des. N.L. fem. adj. *asteroides* (from Gr. adj. *asteroeides -es*), star-like.

Acid–alcohol-fast actinomycetes which form a branched substrate mycelium that fragments into coccoid to rod-shaped elements. An orange to red substrate mycelium carries sparse to white aerial hyphae. Grows at 30°C but not at 45°C. Proline is used as simultaneous carbon and nitrogen source, but not acetamide, L-alanine, gelatin, or serine. 2-Deoxythymidine-5′-*p*-nitroanilide (*p*NA) phosphate, *p*-nitrophenyl (pNP) phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Susceptible to amikacin, and amoxicillin-clavulanic acid, but

is resistant to ampicillin, cefulaxime, cefuroxime, chloramphenicol, clindamycin, erythromycin, gentamicin, kanamycin, minocycline, perfloxacin, tetracycline, sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole (Boiron and Provost, 1988b). The type strain is sensitive (in μg/ml) to bacitracin (100) and polymyxin (5), but is resistant to amoxicillin (10), ampicillin (5), cephaloridine (10), doxycycline (10), erythromycin (10), kanamycin (5), lincomycin (10), lividomycin (10), neomycin (10), novobiocin (100), paromomycin (100), penicillin (10), streptomycin (10), and sulfamethoxazole (100) (Hamid et al., 2001b) and is sensitive to (in μg/ml per disc) imipenem (2.5) and tobramycin (2.5), slightly sensitive to kanamycin (30), but resistant to 5-fluorouracil (Kageyama et al., 2005d). Grows in the presence (%, w/v) of sodium chloride (5), but is inhibited by pyronin G (0.1), sodium azide (0.01), sodium chloride (7), sodium nitrate (0.1), tetrazolium salt (0.1) and thallous acetate (0.001).

Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acid moieties are *N*-glycolated. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{15:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, $C_{18:0}$, and -$C_{19:1}$ *cis*-10, and traces of $C_{14:0}$, -$C_{15:1}$ *cis*10, and $C_{20:0}$. Mycolic acids have 46–60 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty acid methyl esters ($C_{12:0}$–$C_{18:0}$). Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: (i) *Nocardia farcinica* (25%), *Nocardia nova* (27%), *Nocardia salmonicida* (57%), and *Nocardia seriolae* (57%) (Kudo et al., 1988), and (ii) *Nocardia abscessus* (8%), *Nocardia nova* (10%), *Nocardia paucivorans* (9), *Nocardia pseudobrasiliensis* (11%), *Nocardia transvalensis* (12%), *Nocardia vaccinii* (9%), and *Nocardia vinacea* (10%) (Kinoshita et al., 2001).

DNA G+C content (mol%): 63–69 (T_m).

Type strain: ATCC 19247, CCUG 10073, CIP 104503, DSM 43757, IFO (now NBRC) 15531, IMET 7547, JCM 3384, NCTC 11293, NRRL B-3828.

Sequence accession no. (16S rRNA gene): AF430019.

Additional remarks: a range of additional phenotypic properties are cited in extensive numerical taxonomic studies (Goodfellow, 1971; Orchard and Goodfellow, 1980; Tsukamura, 1982a).

2. **Nocardia abscessus** Yassin, Rainey, Mendrock, Brzezinka and Schaal 2000b, 1492[VP]

abs.ces′sus. L. gen. masc. n. *abscessus* of or from an abscess, referring to the characteristic clinical conditions from which the organisms were isolated.

Slightly acid–alcohol-fast actinomycetes which form an extensive, orange colored substrate mycelium that bears abundant white aerial hyphae. Towards the end of the growth cycle filaments fragment into rod-shaped elements. Mature colonies measure 0.5–0.1 mm in diameter. Does not grow at 45°C. Does not hydrolyze 2-deoxythymidine-5-*p*-nitrophenyl (*p*NP) phosphate, *p*NP-phosphorylcholine, or *p*NP-β-D-xyloside. Does not use acetamide, L-alanine, gelatin, proline, or serine as simultaneous carbon and nitrogen sources. Susceptible (μg per disc) to tobramycin (2.5), slightly susceptible to imipenem (10), moderately susceptible to kanamycin (10), but resistant to 5-fluorouracil (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39.

Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{16:1}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and traces of $C_{14:0}$, $C_{15:0}$, $C_{16:0}$10-methyl, $C_{17:0}$, $C_{20:0}$, $C_{20:1}$, and $C_{21:1}$. Mycolic acids have 46–56 carbon atoms with 0–4 double bonds. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty acid methyl esters ($C_{14:0}$ and $C_{16:0}$). The polar lipid and menaquinone profiles are typical for the genus. DNA–DNA relatedness values between *Nocardia abscessus* strains and the type strains of *Nocardia asteroides* and *Nocardia paucivorans* are in the range 23.7–56.8 and 32.0–60.0%, respectively (Yassin et al., 2000b). Similarly, the values between the type strain and corresponding strains of closely related species, namely *Nocardia asteroides, Nocardia nova, Nocardia paucivorans, Nocardia pseudobrasiliensis, Nocardia transvalensis, Nocardia vaccinii*, and *Nocardia vinacea*, fall within the range 4–8% (Kinoshita et al., 2001).

Source (type strain): a joint abscess of a patient with a complete endoprosthesis of one of his knees.

DNA G+C content (mol%): 67.5–69.8.1 (HPLC).

Type strain: ATCC BAA-279, CCUG 45938, CIP 106822, DSM 44432, IMMIB D-1592, JCM 10984, NBRC 100374.

Sequence accession no. (16S rRNA gene): AF218292.

3. **Nocardia acidivorans** Kämpfer, Huber, Buczolits, Thummes, Grün-Wollny and Busse 2007, 1187[VP]

a.cid.i.vo′rans. N.L. n. *acidum* (from L. adj. *acidus* sour) an acid; L. v. *vorare* to devour; N.L. part. adj. *acidivorans* acid-devouring.

A branched substrate mycelium fragments into rod-shaped elements. A light orange substrate mycelium bears yellowish-white aerial hyphae. Grows well on nutrient agar at 25–30°C. L-Alanine-*p*-nitroanilide (*p*NA), *p*-nitrophenyl (*p*NP)-β-D-glucopyranoside, *bis*-*p*NP-phosphate and *p*NP-β-D-xylanopyranoside are hydrolyzed, but not 2-deoxythimidine-5′-*p*NP phosphate, *p*NP-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate, L-glutamate-γ-3 carbonyl *p*NA, *p*NP-phosphorylcholine, or L-proline *p*NA. Additional phenotypic properties are cited in Table 39.

Cellular fatty acids contain major proportions of $C_{15:0}$, $C_{16:0}$, $C_{17:1}$ ω8*c* cis8 and 10-methyl $C_{17:0}$, and smaller proportions (<10%) of $C_{14:0}$, $C_{17:0}$, $C_{15:1}$ *cis*5, $C_{18:1}$ *cis*9, 10-methyl $C_{18:0}$, and 10-methyl $C_{19:0}$. The polar lipid and menaquinone profiles are typical for the genus. DNA–DNA relatedness values between the type strain and the corresponding strains of related species are as follows: *Nocardia jiangsiensis* (50.9%), *Nocardia miyunensis* (41.7%), *Nocardia niigatensis* (11.0%), *Nocardia nova* (62.6%), *Nocardia pseudobrasiliensis*

(46.1%), and *Nocardia uniformis* (21.0%) (Kämpfer et al., 2007).

Source: soil collected from the island of Stramboli, Italy.

DNA G+C content (mol%): not determined.

Type strain: CCUG 53410, CIP 109315, DSM 45049, GW4–1778, JCM 14671.

Sequence accession no. (16S rRNA gene): AM402972.

Additional remarks: the carbon source utilization profile of the type strain and corresponding strains of related species have been reported (Kämpfer et al., 2007).

4. **Nocardia africana** Hamid, Maldonado, Sharaf Eldin, Mohamed, Saeed and Goodfellow 2001b, 1229[VP] (Effective publication: Hamid, Maldonado, Sharaf Eldin, Mohamed, Saeed and Goodfellow 2001a, 627.)

a.fri.ca′na. L. fem. adj. *africana* African, of Africa, the source of the isolates.

Acid–alcohol-fast actinomycetes which form a branched substrate mycelium that fragments into irregular rod-shaped elements. Sparse white aerial hyphae are occasionally seen. Orange wrinkled colonies are formed on glucose-yeast extract agar. Does not produce diffusible pigments. Grows at 20–45°C. L-Alanine is used as a simultaneous carbon and nitrogen source, but not acetamide, gelatin, proline, or serine. Susceptible (μg/ml) to bacitracin (100), cephaloridine (10), gentamicin (10), kanamycin (5), lincomycin (10), lividomycin (100), paromomycin (100), polymyxin (5), streptomycin (100), and sulfamethoxazole (100), but not to amoxicillin (10), ampicillin (5), cephaloridine (100), doxycycline (10), erythromycin (100), gentamicin (100), lincomycin (100), neomycin (100), novobiocin (10), penicillin (100), and spiramycin (5) (Hamid et al., 2001b), and susceptible to (μg per disc) 5-fluorouracil (30), imipenem (2.5), kanamycin (5.0), and tobramycin (10) (Kageyama et al., 2005d). Grows in the presence (%, w/v) of sodium nitrate (0.1), tetrazolium salt (0.1) and thallous acetate (0.001), but is inhibited by pyronin G (0.1), sodium azide (0.01), and sodium chloride (7). Additional phenotypic properties are cited in Table 39.

Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{16:1}$ *cis*9, and $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer-chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical for the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: (i). *Nocardia vinacea* (Alburquerque de Barros et al., 2003), and (ii) *Nocardia cerradoensis* (12%), *Nocardia nova* (2%), *Nocardia vaccinii* (10%), *Nocardia vermiculata* (4%), *Nocardia veterana* (4%), and *Nocardia vinacea* (2) (Kageyama et al., 2004c).

Source: sputa of patients with pulmonary disease.

DNA G+C content (mol%): not determined.

Type strain: SD 769, ATCC BAA-280, CCUG 46122, DSM 44491, JCM 11438, NBRC 100379, NCTC 13181.

Sequence accession no. (16S rRNA gene): AF430054.

5. **Nocardia alba** Li, Jiang, Kroppenstedt, Xu and Jiang 2004b (Effective publication: Li, Jiang, Kroppenstedt, Xu and Jiang, 2004a, 310.)

al′ba. L. fem. adj. *alba* white color.

Substrate and aerial hyphae fragment irregularly into rod-shaped elements. Grows well on glucose-asparagine, inorganic salts-starch, oatmeal, and yeast extract-malt extract agars (ISP media 5, 4, 3, and 2, respectively); diffusible pigments are not produced on any of these media. Pinkish white aerial mycelium and yellow-white substrate mycelium are formed on ISP media 3 and 4. Optimal growth temperature and pH are 28°C and pH 7.0, respectively. Susceptible (μg per disc) to 5-fluorouracil (30), impenem (2.5), kanamycin (5.0), and tobramycin (2.5), and 5-fluorouracil (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39.

Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The predominant fatty acids are $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl. Mycolic acids have 48–56 carbon atoms with C52 as the major component. The polar lipid and menaquinone profiles are typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia ninae*, a closely related species, is below 20% (Laurent et al., 2007).

Source: soil collected in Yunnan Province, China.

DNA G+C content (mol%): 74 (T_m).

Type strain: CCTCC AA 001030, DSM 44684, JCM 13373, YIM 30243.

Sequence accession no. (16S rRNA gene): AY222321.

Additional remarks: the type strain CCTCC AA 001030 was cited as CCTCC AA001030 in the effective publication (Lists Editor, 2004b).

6. **Nocardia altamirensis** Jurado, Boiron, Kroppenstedt, Laurent, Couble. Laiz Klenk, González, Saiz-Jimenez, Mouniée, Bergeron and Rodriguez-Nava 2008, 2212[VP]

al.ta.mi.ren′sis. N.L. fem. adj. *altamirensis* of or belonging to the Altamira cave, Cantabria, Spain, where the type strain was isolated.

Slightly acid–alcohol-fast actinomycete. Forms a branched substrate mycelium that fragments into irregular coccoid to rod-shaped elements. The substrate mycelium is yellowish-orange and the aerial mycelium white but with a patchy distribution. Colonies are 2–3 mm in diameter on Bennett's agar. Grows well at 30°C, but does not grow at 45°C. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$, and $C_{18:0}$ 10-methyl. Mycolic acids have 52–58 carbon atoms. The menaquinone profile is typical of the genus. The type strain and the corresponding strain of *Nocardia tenerifensis* share a DNA–DNA relatedness of 29.0% (Jurado et al., 2008).

Source (type strain): The Altamira cave, Cantabria, Spain.

DNA G+C content (mol%): 64.4 (T_m).

Type strain: CIP 109606, DSM 44997, JCM 14670, OFM S17.

Sequence accession no. (16S rRNA gene): EU006090.

7. **Nocardia amamiensis** Yamamura, Tamura, Sakiyama and Harayama 2007, 1601[VP]

a.ma.mi.en′sis. N.L. fem. adj. *amamiensis* of or pertaining to Amami Island, the source of the isolate.

Partially acid–alcohol-fast actinomycete which forms moderate white aerial hyphae on modified Bennett's agar. Does not produce diffusible pigments. Grows between 15 and 37°C, but not at 10 or 45°C. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$, $C_{18:1}$ *cis*9, and 10-methyl-$C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer-chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The polar lipid and menaquinone profiles are typical for the genus.

DNA–DNA relatedness values between the type strain and corresponding strains of related species are: *Nocardia araoensis* (18.3%), *Nocardia arthritidis* (20.3%), *Nocardia beijingensis* (6.9%), and *Nocardia pneumoniae* (20.3%) (Yamamura et al., 2007).

Source: a soil sample collected from a sugar-cane field on Amami Island, Japan.

DNA G+C content (mol%): 67.4 (HPLC).

Type strain: DSM 45066, JCM 14877, KCTC 19208, NBRC 102102, TT 00–78.

Sequence accession no. (16S rRNA gene): AB275164.

8. **Nocardia anaemiae** Kageyama, Yazawa, Nishimura and Mikami 2005b, 1396[VP] (Effective publication: Kageyama, Yazawa, Nishimura and Mikami 2005c, 25.)

a.na.e.mi′a.e. N.L. fem. n. anemiae, from Gr. fem. n. *anaimia* want of blood, N.L. gen. n. *anaemiae* of anaemia, referring to the disease of the patient with this condition.

Acid-fast actinomycetes which form a branched, pale substrate mycelium that fragments into irregular rod-shaped elements. White aerial hyphae are formed on brain heart infusion agar. Colonies are 0.2–0.3 mm in diameter on Mueller–Hinton II agar supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Susceptible (μg per disc) to impenem (2.5) and tobramycin (2.5), but not to 5-fluorouracil (30) (Kageyama et al., 2005c). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia vinacea*, a closely related species, is 56% (Kageyama et al., 2005d).

Source (type strain): a patient with a history of autoimmune hemolytic anemia and steroid therapy.

DNA G+C content (mol%): 66.2 (HPLC).

Type strain: DSM 44821, IFM 0323, JCM 12396, NBRC 100462.

Sequence accession no. (16S rRNA gene): AB162801.

9. **Nocardia aobensis** Kageyama, Suzuki, Yazawa, Nishimura, Kroppenstedt and Mikami 2005b, 547[VP] (Effective publication: Kageyama, Suzuki, Yazawa, Nishimura, Kroppenstedt and Mikami 2004d, 821.)

a.o.ba.en′sis. N.L. fem. adj. *aobensis* of or pertaining to Aobacho, Chiba, Japan, where the type strain was isolated.

Partially acid–alcohol-fast actinomycetes which produce an orange to dull-orange substrate mycelium. Does not form visible hyphae on most standard media, though short spore chains can be seen. Colonies are 0.3–3.0 mm in diameter on Mueller–Hinton II agar supplemented with glucose and glycerol (each at 1%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Moderately susceptible (μg per disc) to impenem (5.0), slightly susceptible to kanamycin (30), but is resistant to 5-fluorouracil (10) and tobramycin (10) (Kageyama et al., 2004d). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, $C_{18:0}$, and 10-methyl $C_{18:0}$, and smaller proportions (<10%) of $C_{14:0}$ and $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between *Nocardia aobensis* strains and the type strains of related species are as follows: *Nocardia africana* (44–48%), *Nocardia cerradoensis* (58–65%), and *Nocardia veterana* (12–24%) (Kageyama et al., 2004d).

Source: clinical material.

DNA G+C content (mol%): 67–68 (HPLC).

Type strain: DSM 44805, IFM 0372, JCM 12352, NBRC 100429.

Sequence accession no. (16S rRNA gene): AB126876.

Additional remarks: the specific epithet, *aobensis*, is a N.L. fem. adj., not a N.L. fem. n. as stated in the effective publication.

10. **Nocardia araoensis** Kageyama, Yazawa, Mukai, Kohara, Nishimura, Kroppenstedt and Mikami 2004g, 2028[VP]

a.ra.o.en′sis. N.L. fem. adj. *araoensis* of or belonging to Arao City, where the bacterium was isolated.

Partially acid-fast actinomycetes which produce a branched, faint yellow substrate mycelium that fragments into rod-shaped elements (0.3–0.5 × 1.0–1.7 μm). Forms a cotton white to grayish white aerial mycelium but does not produce diffusible pigments. Colonies 0.5–1.4 mm in diameter are formed on Mueller–Hinton II medium supplemented with glycerol (0.2% w/v) after 7 d at 30°C. Grows at 37 and 45°C. Slightly susceptible (mg per disc) to impenem (10.0 and kanamycin (30) (Kageyama et al., 2004g). Additional phenotypic properties are cited in Table 39. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, $C_{16:1}$ *cis*7, and $C_{18:1}$ *cis*9, smaller proportions (<10%) of $C_{14:0}$, $C_{18:0}$, $C_{18:0}$ 10-methyl, and $C_{18:1}$ *cis*9, and traces of $C_{15:0}$, $C_{16:1}$ *cis*9, $C_{19:1}$ *cis*11, $C_{19:0}$, and $C_{20:1}$ *cis*11. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus.

DNA–DNA relatedness values between the type strain and the corresponding strains of related species are as follows: *Nocardia beijingensis* (<46%), and *Nocardia pneumoniae* (35%) (Kageyama et al., 2004g).

Source (type strain): sputum of a patient with a history of lung cancer, diabetes, emphysema, and radiation pneumonia.

DNA G+C content (mol%): 69 (HPLC).

Type strain: DSM 44729, IFM 0575, JCM 12118, NBRC 100135.

Sequence accession no. (16S rRNA gene): AB108779.

11. **Nocardia arthritidis** Kageyama, Torikoe, Iwamoto, Masuyama, Shibuya, Okazaki, Yazawa, Minota, Kroppenstedt and Mikami 2005a, 1[VP] (Effective publication: Kageyama, Torikoe, Iwamoto, Masuyama, Shibuya, Okazaki, Yazawa, Minota, Kroppenstedt and Mikami 2004e, 2370.)

ar.thri′ti.dis. Gr. n. *arthritis -idos* gout, arthritis; N.L. gen. n. *arthritidis* of arthritis.

Acid–alcohol-fast actinomycete. Forms an orange, branched substrate mycelium that fragments into irregular rod-shaped elements (0.5–0.6 × 1.4 × 1.7 µm). Pale orange aerial hyphae are formed on brain heart infusion agar. Does not produce melanin pigments on standard agar media. Colonies 0.5–1.2 mm in diameter are formed on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows best at 45°C. Susceptible (mg per disc) to tobramycin (2.5), moderately susceptible to impenem (5.0) and kanamycin (10), and resistant to 5-fluorouracil (10) (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{16:1}$ *cis*8, and $C_{16:1}$ *cis*9, and traces of $C_{15:0}$, $C_{16:1}$ *cis*7, and 10-methyl-$C_{16:0}$. The menaquinone profile is typical of the genus, as is the presence of mycolic acids. The DNA–DNA relatedness values between the type strain and the corresponding strain of *Nocardia beijingensis*, a closely related species, is within the range of 14–17% (Kageyama et al., 2004e).

Source (type strain): sputum of a patient with rheumatoid arthritis and lung nocardiosis.

DNA G+C content (mol%): 68 (HPLC).

Type strain: DSM 44731, IFM 10035, JCM 12120, NBRC 100137.

Sequence accession no. (16S rRNA gene): AB108781.

Additional remarks: the strains DSM 44731 and JCM 12120 were only cited in the abstract of the effective publication, but the authors did provide certificates of deposition from these collections (Lists Editor, 2005).

12. **Nocardia asiatica** Kageyama, Poonwan, Yazawa, Mikami and Nishimura 2004b, 127[VP]

a.si.a′ti.ca. L. fem. adj. *asiatica* of Asia, the source of the isolates

Partially acid-fast actinomycetes. Form a beige substrate mycelium which undergoes fragmentation. Straight to flexuous aerial hyphae differentiate into chains of 2–20 cylindrical spores (0.3–0.5 × 1.5–1.7 µm). Colonies 0.3–1 mm in diameter are formed on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v). Grows at 37°C, but not at 45°C. Susceptible (µg per disc) to imipenem (2.5) and tobramycin (2.5); moderately susceptible to kanamycin (10), but resistant to 5-fluorouracil (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Two kinds of mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-cell methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strains of *Nocardia asiatica* and *Nocardia beijingensis*, a closely related species, is within the range of 33–39% (Kageyama et al., 2004b).

Source: clinical material.

Source (type strain): sputum of a patient with nocardiosis.

DNA G+C content (mol%): 68.4–69.9 (HPLC).

Type strain: CCUG 48826, DSM 44668, IFM 0245, JCM 11892, NBRC 100129.

Sequence accession no. (16S rRNA gene): AB092566.

Additional remarks: the specific epithet *asiatica* is a N.L. fem. adj., not a L. gen. masc. n. as cited in the paper by Kageyama et al. (2004b).

13. **Nocardia beijingensis** Wang, Zhang, Lu, Shi, Liu, Maldonado and Goodfellow 2001, 1785[VP]

bei.jing.en′sis. N.L. fem. adj. *beijingensis* of or pertaining to Beijing, the source of the isolate.

Slightly acid–alcohol-fast actinomycete. Forms an orange, branched substrate mycelium that fragments *in situ* into irregular rod-shaped elements and carries sparse to abundant aerial hyphae on modified Sauton's agar. Short chains of up to four spores are formed on aerial and substrate hyphae. Does not produce diffusible pigments. Colony elevation is convex to irregular and colony margins filamentous. Does not grow at 45°C. L-Alanine-*para*-nitroanilide (*p*NA), 2-deoxythymidine-5-*p*-nitrophenyl (*p*NP) phosphate, *bis*-*p*NP-phosphate, and *p*NP-phenylphosphonate are hydrolyzed, but not *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *p*NP-glucuronide, L-glutamate-γ-3-carboxyl, *o*-nitrophenyl-β-D-galactopyranoside, *p*NP-phosphorylcholine, L-proline *p*NA, and *p*NP-β-D-xylopyranoside. L-Alanine, L-aspartate, L-glutamate, monoethanolamine, L-proline, uric acid, and L-valine are used as simultaneous carbon and nitrogen sources, but not acetamide, gelatin, L-leucine, L-phenylalanine, or urea. Susceptible (µg/ml per disc) to imipenem (2.5), kanamycin (5.0), and tobramycin (2.5), but not to 5-fluorouracil (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{16:1}$ *cis*9, and $C_{17:1}$ *cis*9, and traces of $C_{16:1}$ *cis*7, $C_{16:1}$ *cis*8, $C_{16:1}$ *cis*11, $C_{19:1}$ *cis*9, $C_{19:0}$, and C_{20} *cis*11. Two types of mycolic acids co-migrate on one-dimensional thin-layer-chromatography of whole-organism methanolysates with those of reference *Nocardia*

strains. The menaquinone profile is typical of the genus. The DNA–DNA relatedness value between the type strain and corresponding strain of *Nocardia tenerifensis*, a closely related species, is 16.8% (Kämpfer et al., 2004).

Source (type strain): a mud sample taken from a sewage ditch at Xishain mountain in Beijing.

DNA G+C content (mol%): 69 (T_m).

Type strain: O2, AS4.1521, CCUG 46096, DSM 44636, IFO (now NBRC) 16342, JCM 10666.

Sequence accession no. (16S rRNA gene): AF154129.

Additional remarks: the specific epithet is a N.L. feminine adjective, not a N.L. masculine adjective as cited in the paper by Wang et al. (2001).

14. **Nocardia blacklockiae** Conville, Brown, Steigerwalt, Brown-Elliott and Witebsky 2009, 1 (Effective publication: Conville, Brown, Steigerwalt, Brown-Elliott and Witebsky 2008, 1183.)

black.loc.ki′a.e. N.L. fem. gen. n. *blacklockiae* of Blacklock, in memory of Zeta M. Blacklock, in honor of and in recognition of her contributions to the study of *Nocardia* taxonomy.

Acid-fast actinomycetes. Form a branched substrate mycelium which carries aerial hyphae. Grows at 25°C and 35°C, but not at 45°C. The type strain is susceptible to amoxicillin-clavulanic acid, cefriaxine and linezolid, but is resistant to amikacin and clarithromycin. Does not use acetamide as a simultaneous carbon and nitrogen source. Additional phenotypic properties are cited in Table 39. DNA–DNA relatedness values between the type strain and those of corresponding strains of closely related species are as follows: *Nocardia transvalensis* (34%+8.5% divergence) and *Nocardia wallacei* (45%+7.5% divergence) (Conville et al., 2008). The organism is a pathogen of immunocompromised patients.

DNA G+C content (mol%): not determined.

Type strain: ATCC 700035, DSM 45135.

Sequence accession no. (16S rRNA gene): EU099360.

Additional remarks: the taxonomic status of *Nocardia blacklockiae* is supported by DNA–DNA homology data and by results from 65-kDa heat-shock protein and *secA1* gene sequence analyses (Conville et al., 2008).

15. **Nocardia brasiliensis** (Lindenberg 1909) Pinoy 1913, 337[AL]. ["*Discomyces brasiliensis* (Lindenberg 1909) Sartory 1920; "*Actinomyces brasiliensis*" (Lindenberg 1909) Gomes 1923: "*Actinomyces violaceus* subsp. *brasiliensis*" Krasil'nikov 1941.]

bra.si.li.en′sis. N.L. fem. adj. *brasiliensis* of or pertaining to Brazil.

Weakly acid-fast actinomycetes. Form pinkish or orange-tan to tan or brown substrate mycelia which carry moderate to abundant, nonfragmenting aerial hyphae that are usually off-white to pink-gray in color. Soluble dark pigments are usually formed. Grows well at 30°C and 45°C. L-Alanine-*p*-nitroanilide (*p*NA), 2-deoxythymidine-5′-*p*-nitrophenyl (*p*NA) phosphate, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3 carbonyl *p*NA, *bis-p*NP-phosphate, *p*NP-phenylphosphonate, *p*NP-phosphorylchloine, L-proline *p*NA and *p*NP-β-D-xylopyranoside are hydrolyzed, but not *p*NP-β-D-glucuronide or *o*-nitrophenyl-β-D-galactosidase. L-Alanine, gelatin, proline, and serine are used as simultaneous carbon and nitrogen sources, but not acetamide. Susceptible to amikacin, amoxicillin + clavulanic acid, gentamicin and minocycline, but resistant to ampicillin, cefuroxime, cefotaxime, chloramphenicol, clindomycin, erythromycin, kanamycin, pefloxacin, sulfonomides, tetracycline, trimethoprim, and trimethoprim-sulfamethoxazole (Boiron and Provost, 1988b). The type strain is sensitive (μg/ml) to amoxicillin (100), bacitracin (100), gentamicin (10), kanamycin (5), lincomycin (10), novobiocin (10), polymyxin (5), and sulfamethoxazole (100), but resistant to ampicillin (5), cephaloridine (100), doxycycline (10), erythromycin (100), gentamicin (100), kanamycin (50), lincomycin (100), lividomycin (100), neomycin (100), novobiocin (100), paromomycin (100), penicillin (10), spiramycin (50), and streptomycin (100) (Hamid et al., 2001b), and sensitive to (μg ml per disc) tobramycin (2.5), but not to 5-fluorouracil (30), imipenem (10), and kanamycin (30) (Kageyama et al., 2005d). Grows in the presence (%, w/v) of sodium chloride (5), sodium nitrate (0.1), tetrazolium salt (0.1) and thallous acetate (0.001), but is inhibited by pyronin G (0.1), sodium azide (0.01), and sodium chloride (7). Additional phenotypic properties are shown in Table 39.

Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9 and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:0}$, and $C_{18:0}$, and traces of $C_{10:0}$, $C_{12:0}$, $C_{16:1}$ *cis*9, $C_{17:1}$ *cis*9, and $C_{15:1}$ anteiso. Muramic acid moieties are *N*-glycolated. Mycolic acids have 46–60 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty acid methyl esters ($C_{12:0}$–$C_{18:0}$). Menaquinone and polar lipid profiles are typical of the genus. Grows in the presence (%, w/v) of sodium chloride (5), sodium nitrate (0.1), tetrazolium salt (0.1), and thallus acetate (0.001). Growth is inhibited by pyrosin G (0.1), sodium azide (0.01), and sodium chloride (7). The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia tenerifensis*, a closely related species, is 26.2% (Kämpfer et al., 2004).

Source: patients with nocardioses and mycetoma, and occasionally from soil.

DNA G+C content (mol%): 67–68 (T_m).

Type strain: ATCC 19296, CCUG 10098, CIP 104502, DSM 43758, JCM 3374, IFO (now NBRC) 14402, NCTC 11294, VKM Ac-863.

Sequence accession no. (16S rRNA gene): AF430038.

16. **Nocarnudia brevicatena** (Lechevalier, Solotorovsky and McDurmont 1961) Goodfellow and Pirouz 1982a, 384[VP] (Effective publication: Goodfellow and Pirouz 1982b, 523; basonym: *Micropolyspora brevicatena* Lechevalier, Solotorovsky and McDurmont 1961, 13[AL])

bre.vi.ca.te′na. L. adj. *brevis* short; L. n. *catena* chain; N.L. n. *brevicatena* short chain (of spores).

White to yellowish substrate mycelium carry aerial hyphae. Single or short chains of spores (2–10) are formed either directly or on short sporophores on both substrate and aerial hyphae. Spores are oblong, sometimes pyriform,

and are about 1.5 μm in diameter. Aerial hyphae are often aggregated into long filamentous sheaths. Abundant, slightly wrinkled, pale orange growth occurs on casein hydrolysate-glycerol agar. Growth on yeast extract agar is thin, pale orange with white powdery aerial hyphae. Grows well at 36°C and pH 6.3, but not at 45°C or pH 5.1. Susceptible (μg ml per disc) to chloramphenicol (5), neomycin (5), and streptomycin (100) (Lechevalier et al., 1961). Susceptible (μg ml per disc) to kanamycin (5.0) and tobramycin (2.5), slightly susceptible to imipenem (10), but not to 5-fluorouracil (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acid moieties are *N*-glycolated. Mycolic acids have 46–60 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty acid methyl esters. Menaquinone and polar lipid profiles are typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia paucivorans*, a closely related species, is 61.9% (Yassin et al., 2000a).

DNA G+C content (mol%): not determined.

Type strain: ATCC 15333, CCUG 46115, CIP 104508, DSM 43024, IFO (now NRBC) 12119, IMET 9542, IMRU 1086W, JCM 3029, NRRL B-2896, RIA 709, VKM Ac-936.

Sequence accession no. (16S rRNA gene): AF430040.

17. **Nocardia caishijiensis** Zhang, Liu and Goodfellow 2003, 1003[VP]

cai.shi.ji.en′sis. N.L. fem. adj. *caishijiensis* of or belonging to Caishiji, the source of the soil from which the type strain was isolated.

Slightly acid–alcohol-fast actinomycete. Forms an extensively branched substrate mycelium that fragments *in situ* into rod-shaped elements. An orange to brown substrate mycelium carries sparse to abundant white to pinkish aerial hyphae on modified Sauton's agar. A brown substrate mycelium and white to grayish aerial hyphae are formed on modified Bennett's agar. Does not produce diffusible pigments. Colony elevation is convex to irregular and colony margins are filamentous. Grows at 17–37°C, but not at 45°C, and at pH 5.2–10.0. L-Alanine, L-aspartate, D-glucosamine, L-proline, and L-serine are used as simultaneous carbon and nitrogen sources, but not acetamide, L-asparagine, gelatin, L-leucine, L-phenylalanine, or L-valine. Susceptible (μg ml per disc) to chloramphenicol (20), erythromycin (15), midecamycin (15), minocycline (30), rifampin (5), tobramycin (10), and vancomycin (30), but not to gentamicin (10), penicillin (G), and streptomycin (10) (Zhang et al., 2003). Susceptible (μg per disc) to 5-fluorouracil (30) and imipenem (2.5) but not to kanamycin (30) and tobramycin (2.5) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:0}$, *C16:1 cis9* and $C_{18:1}$ *cis*9, and smaller proportions (<10%) of $C_{15:0}$, $C_{17:0}$, $C_{17:1}$ *cis*9, $C_{20:2}$ *cis*11,14, and $C_{18:0}$ 10-methyl. Menaquinone and polar lipid profiles are typical of the genus, as is the presence of mycolic acids in whole-organism methanolysates.

Source (type strain): a soil sample collected in Caishiji, Anshii Province, China.

DNA G+C content (mol%): 69.4 (T_m).

Type strain: AS 4.1728, F829, JCM 11508.

Sequence accession no. (16S rRNA gene): AF459443.

18. **Nocardia callitridis** Kaewkla and Franco 2010, 1534[VP]

cal.li′tri.dis. N.L. gen. n. *callitridis* of *Callitris*, the botanical name of a genus of pine, named after the source plant of the type strain, the Australian native pine *Callitris preissii*.

Non-acid–alcohol-fast actinomycete which forms an extensive substrate mycelium which fragments into rod-shaped elements. A pale orange substrate mycelium bears white to orange white aerial hyphae on Bennett's, half strength potato-dextrose, and yeast extract-malt extract (ISP medium 2) agars. A brownish-orange diffusible pigment is produced on glucose-asparagine agar (ISP medium 5). Grows at 15–32°C and pH 5.0–10.0, but not at 37°C or pH 4.0. Grows in the presence of 5%, w/v sodium chloride. Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{16:1}$ *cis*7, $C_{16:1}$ *cis*6, and $C_{18:0}$, and traces of *iso*- and $C_{17:1}$ *cis*10, and *anteiso*- and $C_{17:1}$ *cis*9. The menaquinone profile is typical of the genus, as is the presence of mycolic acids in whole-organism methanolysates.

Source (type strain): internal tissues of a surface sterilized root of an Australian pine tree, *Callistris preisii.*

DNA G+C content (mol%): 68.7 (HPLC).

Type strain: ACM 5287, CAP 290, DSM 45353.

Sequence accession no. (16S rRNA gene): FJ805428.

19. **Nocardia carnea** (Rossi-Doria 1891) Castellani and Chalmers 1913, 337[VP] ("*Streptothrix carnea*" Rossi-Doria 1891)

car′ne.a. L. fem. adj. *carnea* of flesh.

Rarely acid-fast actinomycete. Forms a peach colored substrate mycelium that carries sparse to abundant pinkish aerial hyphae. Some strains have been reported to bear rudimentary spores on the aerial mycelium. Soluble pigments may be produced. Grows at 30°C, but not at 45°C. 2-Deoxythymidine-5′-*para*-nitrophenyl (*p*NP) phosphate, *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Susceptible (μg per disc) to imipenem (2.5), kanamycin (5.0), and tobramycin (2.5), but not to 5-fluorouracil (30) (Kageyama et al., 2005d). Does not use L-phenylalanine or L-valine as simultaneous carbon and nitrogen sources. Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acid moieties are *N*-glycolated.

Source: soil and air.

DNA G+C content (mol%): 64–68 (T_m).

Type strain: ATCC 6847, CCUG 48177, CIP 104509, DSM 43397, IFO (now NRBC) 14403, IMET 7504, JCM 3375, NCTC 3527, NRRL B-1336, NRRL WC-3809, VKM Ac-814.

Sequence accession no. (16S rRNA gene): AF430035.

20. **Nocardia cerradoensis** Albuquerque de Barros, Manfio, Ribeiro Maitan, Mendes Bataus, Kim, Maldonado and Goodfellow 2003, 32[VP]

cer.ra.do.en′sis. N.L. fem. adj. *cerradoensis* of or pertaining to Cerrado soil, the source of the organism.

Slightly acid–alcohol-fast actinomycete. Forms an extensively branched substrate mycelium that fragments *in situ* into rod-shaped elements. Pinkish white aerial hyphae are formed. Orange to tan colonies are produced on modified Bennett's agar. Does not produce diffusible pigments. Colony elevation is convex to regular and colony margins are filamentous. Grows well at 30°C but does not grow at 45°C. L-Glutamate, L-leucine, L-proline, and L-valine are used as simultaneous carbon and nitrogen sources, but not acetamide, L-aspartic acid, gelatin, monoethanolamine, L-phenylalanine, uric acid, or urea. Susceptible (μg/ml per disc) to imipenem (2.5), kanamycin (5.0), but not to 5-fluorouracil (30) and tobramycin (10) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis9*, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:0}$, $C_{18:0}$, $C_{19:1}$ *cis*10, $C_{20:1}$, and $C_{20:0}$, and traces of $C_{14:0}$, $C_{15:0}$, $C_{17:1}$ *cis*9, and 10-methyl $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer-chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinones and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia africana* (11%), *Nocardia nova* (10%), *Nocardia vaccinii* (41%), *Nocardia veterana* (37%), *Nocardia vinacea* (13), and *Nocardia vermiculata* (9%) (Kageyama et al., 2004c).

Source (type strain): cerrado soil in Brazil.

DNA G+C content (mol%): 68.8 (HPLC).

Type strain: CCT 5601, DSM 44546, JCM 12209, NBRC 101014, Y9.

Sequence accession no. (16S rRNA gene): AF060790.

Additional remarks: the first authors name (Albuquerque de Barros) is incorrectly cited as Alburquerque de Barros in the Author Index (IJSEM, 2003, 53, part 1, p. VII). In addition, the author's name Ribeiro Maitan is incorrectly cited as V. Ribiero Maitan on page 29 but cited correctly in the table of contents (IJSEM, 2003, 53; part 1, p. 1).

21. **Nocardia concava** Kageyama, Yazawa, Taniguchi, Chibana, Nishimura, Kroppenstedt and Mikami 2005d, 2083[VP]

con.ca′va. L. fem. adj. *concava* hollow, concave, referring to the colony morphology on agar plates.

Acid–alcohol-fast actinomycetes. Form a grayish-orange to faint-orange substrate mycelium that fragments into irregular rod-shaped elements. Aerial hyphae, when present, are sparse. Colonies 1.0–3.5 mm in diameter are produced on Mueller–Hinton agar supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Susceptible (μg ml per disc) to 5-fluorouracil (30), kanamycin (2.5), and tobramycin (2.5), but not to imipenem (10) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{15:1}$ *cis*7, $C_{15:1}$ *cis*10, $C_{15:0}$, $C_{16:1}$ *cis*7, $C_{17:1}$ *cis*9, $C_{17:0}$, 10-methyl-$C_{17:0}$, $C_{18:1}$ *cis*9, and -$C_{19:1}$ *cis*9, and traces of $C_{18:0}$ 10-methyl, -$C_{18:1}$ *cis*11, $C_{18:0}$, $C_{19:0}$, 10-methyl-$C_{19:0}$, and $C_{20:1}$. Mycolic acids have 52–62 carbon atoms with C54 and C56 as major components. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between *Nocardia concava* strains and the type strain of *Nocardia seriolae*, a closely related species, is within the range of 12–16% (Kageyama et al., 2005c).

Source: Japanese patients.

DNA G+C content (mol%): 67–68 (HPLC).

Type strain: DSM 44804, IFM 0354, JCM 12351, NBRC 100430.

Sequence accession no. (16S rRNA gene): AB126880.

22. **Nocardia coubleae** Rodríguez-Nava, Khan, Pötter, Kroppenstedt, Boiron and Laurent 2007, 1485[VP]

cou′ble.ae. N.L. gen. fem. n. *coubleae* of Couble, named after Andrée Couble, in recognition of her contribution to the French Nocardiosis Observatory, Lyon, France.

Acid–alcohol-fast actinomycetes. Produce a white substrate mycelium which bears sparse to abundant white aerial hyphae on Bennett's agar. Colonies 1–2 mm in diameter are formed. Grows at 25–37°C, but not at 45°C. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$, $C_{18:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:0}$, $C_{17:1}$, and $C_{18:1}$, and traces of $C_{10:0}$ and $C_{15:1}$. Mycolic acids have 52–58 carbons with C56 as the major component. The menaquinone profile is typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia ignorata*, a closely related species, is 26% (Rodriguez-Nava et al., 2007).

Source: oil contaminated soil collected in Kuwait.

DNA G+C content (mol%): not determined.

Type strain: CIP 108996, DSM 44960, JCM 15318, OFN N12.

Sequence accession no. (16S rRNA gene): DQ235688.

23. **Nocardia crassostreae** Friedman, Beaman, Chun, Goodfellow, Gee and Hedrick 1998, 244[VP]

cras.sos.tre′a.e. N.L. n. *Crassostrea* generic name of Pacific oyster; N.L. gen. n. *crassostreae* of *Crassostrea*, referring to the source of the organism.

Acid-fast actinomycetes. Form an extensive branched substrate mycelium which fragments into irregular rod-shaped elements. Colonies on brain heart infusion agar are dry, waxy, and wrinkled, and do not carry aerial hyphae. Grows at 22–30°C, at pH 9, but not at 5 or 45°C. L-Valine is used as a simultaneous carbon and nitrogen source, but not L-arginine, lysine, or ornithine. Susceptible to (μg ml^{-1}) 5-fluorouracil (20), mitomycin (57), and rifampin (20), but not to isoniazid (200) (Friedman et al., 1998). Does not grow in the presence of 5%, w/v sodium chloride.

Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Mycolic acids have 46–58 carbons. Pyrolysis gas chromatography of purified mycolic acid methyl esters release both odd and even numbered methyl mycolates within the range of C_{12}–C_{18}. The menaquinone profile is typical of the genus.

Source: diseased, cultured oysters (*Crassostreae gigas*).

DNA G+C content (mol%): 68.6–69.3 (T_m).

Type strain: ATCC 700418, CIP 105895, DSM 44597, JCM 10500, NBRC 100342, NB4H.

Sequence accession no. (16S rRNA gene): AF430049.

24. **Nocardia cummidelens** Maldonado, Hookey, Ward and Goodfellow 2001, 1619[VP] (Effective publication: Maldonado, Hookey, Ward and Goodfellow 2000, 371.)

cum.mi.de′lens. L. n. *cummi* rubber; L. partic. adj. *delens* destroying; N.L. partic. adj. *cummidelens* rubber destroying.

Acid–alcohol-fast actinomycetes. Form an extensively branched substrate mycelium that fragments into coccoid to rod-shaped elements. Pale pink colonies carry sparse aerial hyphae on glucose-yeast extract agar. Does not form diffusible pigments. Colony elevation is convex to irregular and colony margins filamentous. Does not grow at 45°C. 2-Deoxythymidine-5-*p*-nitrophenyl (*p*NP), *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Sensitive (μg/ml) to cephaloridine (16), demethylchlortetracycline (16), gentamicin (8), rifampin (1), streptomycin (16), and tobramycin (1) (Maldonado et al., 2001). Sensitive to (μg per disc) imipenem (2.5), tobramycin (2.5), but not to 5-fluorouracil (30) and kanamycin (30) (Kageyama et al., 2005d). Resistant to lysozyme. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid.

DNA G+C content (mol%): not determined.

Type strain: CCUG 46121, CCUG 46295, CIP 10725, DSM 44490, JCM 11439, NBRC 100378, NCIMB 13758, R89.

Sequence accession no. (16S rRNA gene): AF430052.

25. **Nocardia cyriacigeorgica** Yassin, Rainey and Steiner 2008, 1760[VP] (Effective publication: Yassin, Rainey and Steiner 2001a, 1422.)

cy.ri.a.ci.ge.or′gi.ca. Gr. neut. n. *kuriakon* house of the Lord, church; N.L. neut. n. *cyriacum, cyriaci* church; N.L. fem. adj. *georgica* of or related to St George; N.L. fem. adj. *cyriacigeorgica* related to St George's church, referring to the origin of the name of the German town Gelsenkirchen where the type strain was isolated.

Slightly acid–alcohol-fast actinomycete. Forms an extensive branched substrate mycelium that fragments into rod-shaped elements at a late stage of growth. The substrate mycelium bears white aerial hyphae. Acetamide is used as a simultaneous carbon and nitrogen source, but not L-alanine, L-proline, or L-serine. Susceptible (μg per disc) to imipenem (2.5) and tobramycin (2.5), but not to 5-fluorouracil (30) and kanamycin (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:1}$ *cis*7, $C_{18:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{16:0}$ *cis*7, $C_{17:0}$, $C_{18:1}$ *cis*9, $C_{21:0}$, and traces of $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, $C_{16:1}$ *cis*, $C_{17:0}$ 10-methyl, $C_{19:0}$, and $C_{21:1}$. Mycolic acids have 46–54 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of the purified methyl mycolates of the type strain release fatty acid methyl esters with C_{14}–C_{18} carbons. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding closely related strains are as follows: *Nocardia abscessus* (45%) and *Nocardia paucivorans* (32%) (Yassin et al., 2001a).

Source (type strain): the bronchial secretion of a patient with chronic bronchitis.

DNA G+C content (mol%): 68.1 (HPLC).

Type strain: CCUG 48295, DSM 44484, IMMIB D-1627, JCM 11763, NBRC 100375.

Sequence accession no. (16S rRNA gene): AF430027.

Additional remarks: the original spelling of the specific epithet *cyriacigeorgici* (*sic*) was corrected by the Lists Editor, IJSEM (2001). In addition, according to Rules 27(3) and 30 of the Bacteriological Code, this name is not validly published in the effective publication; it only documents the deposit of the type strain in a single recognized culture collection (Euzéby and Tindall, 2004). However, according to Judicial Opinion 81 (2008), *Nocardia cyriacigeorgica* corrig. Yassin et al. 2001a is considered to be validly published.

26. **Nocardia elegans** Yassin and Brenner 2005, 1508[VP]

e′le.gans. L. fem. adj. *elegans* fastidious (with respect to utilization of nutrients).

Partially acid–alcohol-fast actinomycetes. Form an extensive irregularly branched orange substrate mycelium that bears white aerial hyphae. At a late stage of growth hyphae fragment into rod-shaped elements. Grows from 22–42°C. Does not use acetamide, arginine, gelatin, ornithine, proline, or serine as simultaneous carbon and nitrogen sources. Susceptible (μg/ml) to arbekacin (<2), ampicillin (16), clarithomycin (2), cefoticin (8), and erythromycin (4) (Iida et al., 2006). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:0}$, $C_{18:1}$ *cis*9, and $C_{21:0}$, and traces of $C_{14:0}$, $C_{15:0}$, $C_{16:1}$ *cis*7, 10-methyl-$C_{16:0}$, 10-methyl $C_{17:0}$, $C_{18:0}$, $C_{19:0}$, $C_{20:0}$, and $C_{21:1}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Pyrolysis gas chromatography of purified mycolic acid methyl esters release $C_{16:0}$, $C_{18:1}$, and $C_{18:0}$ components. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between *Nocardia elegans* strains and the type strains of closely related species are as follows: *Nocardia africana* (30.2–33.6%) and *Nocardia veterana* (33.6%) (Yassin and Brenner, 2005).

Source: sputa of patients with pulmonary infections.

DNA G+C content (mol%): not determined.

Type strain: CCUG 50200, CIP 108553, IMMIB N-402, JCM 13374.

Sequence accession no. (16S rRNA gene): AJ854057.

27. **Nocardia exalbida** Iida, Kageyama, Yazawa, Uchiyama, Toyohara, Chohnabayashi, Suzuki, Nomura, Kroppenstedt and Mikami 2006, 1195[VP]

ex.al′bi.da. L. fem. adj. *exalbida* whitish or white, referring to the color of the aerial mycelium.

Partially acid–alcohol-fast actinomycetes which produce an extensively branched substrate mycelium that fragments into rod-shaped elements (0.4–0.8 × 0.8–1.7 μm). Orange-tan to tan colonies carry abundant white to off white aerial hyphae. Does not produce soluble pigments. Colonies 1.0–2.8 mm in diameter are formed on Mueller–Hinton medium supplemented with glucose (0.2%, w/v) after 7 d at 37°C. May show weak growth at 45°C. Susceptible (μg/ml) to arbekacin (<2), ampicillin (16), clarithromycin, cefetamet pivoxil (0.5), cefotiam (8), erythromycin (2), and sulfamethoxazole-trimethoprim (152:8) (Iida et al., 2006), and to (μg ml per disc) imipenem (2.5) and tobramycin (2.5). Moderately susceptible to kanamycin (10) but resistant to 5-fluorouracil (Iida et al., 2006). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Two types of mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-cell methanolysates with reference *Nocardia* strains. The major mycolic acids have 48–56 carbon atoms. Fatty acid and menaquinone profiles are typical of the genus. DNA–DNA relatedness values between *Nocardia exalbida* strains and the type strain of *Nocardia xishanensis*, a closely related species, is within the range of 57–59% (Iida et al., 2006).

Source (type strain): the bronchoalveolar lavage of a patient with lung nocardiosis in Japan.

DNA G+C content (mol%): 68 (HPLC).

Type strain: DSM 44883, IFM 0803, JCM 12667, NBRC 100660.

Sequence accession no. (16S rRNA gene): AB187522.

28. **Nocardia farcinica** Trevisan 1889[AL] ["*Streptothrix farcinica*" (Trevisan 1889) Rossi-Doria 1891; "*Bacillus farcinicus*" (Trevisan 1889) Gasperini 1892; "*Actinomyces farcinicus*" (Trevisan 1889) Gasperini 1892; "*Oospora farcinica*" (Trevisan 1889) Sauvageau and Radais 1892; "*Actinomyces bovis farcinicus*" Gasperini 1894; "*Streptothrix farcini bovis*" Kitt 1899, "*Bacterium nocardi*" (*sic*) Migula 1900; "*Streptothrix nocardii*" (Migula 1900) Foulerton and Jones 1901; "*Cladothrix farcinica*" (Trevisan 1889) Macé 1901; "*Bacillus nocardi*" (*sic*) (Migula 1900) Matzuschita 1902; "*Discomyces farcinicus*" (Trevisan 1889) Krasil'nikov 1941]

far. ci′ni.ca. L. n. *farcinimum* a disease of horses; Fr. n. *farcin* farcy or glanders; L. fem. suff. *-ica*, suffix used with the sense of pertaining to; N.L. fem. adj. *farcinica* relating to farcy.

Acid-fast actinomycetes. Form an extensively branched substrate mycelium which fragments into coccoid and rod-shaped elements. An orange to red substrate mycelium carries sparse, grayish aerial hyphae.Grows well at 25–45°C, but not at 10°C, and at pH 6.0–10.0. L-Alanine- *p*-nitroanilide (*p*NA), 2-deoxythymidine-5′*p*-nitrophenyl phosphate (*p*NP), *p*-nitrophenyl (*p*NP)-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3-carbonyl *p*NA, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, *p*NP- phosphorylcholiine, L-proline *p*NA and *p*NP-β-D-xylopyranoside are hydrolyzed, but not *p*NP-β-D-glucuronide or *o*-nitrophenyl-β-D-galactopyranoside. Acetamide is used as a simultaneous carbon and nitrogen source, but not L-alanine, gelatin, proline, or serine. Resistant to ampicillin, cefotaxime, chloramphenicol, clindamycin, sulfonamides, trimethroprim, sulfamethoxazole, but gives variable responses to amikacin, amoxicillin, clavulanic acid, cefuroxime, erythromycin, gentamicin, kanamycin, minocycline, pefloxocin, and tetracycline (Boiron and Provost, 1988b). The type strain is sensitive (μg/ml) to amoxicillin (100), bacitracin (100), cephaloridine (100), erythromycin (100), kanamycin (50), lincomycin (100), novobiocin (10), penicillin (100), polymyxin (5), and streptomycin (100), but is resistant to amoxicillin (10), ampicillin (50), cephaloridine (10), doxycycline (10), erythromycin (10), gentamicin (10), lividomycin (100), neomycin (100), novobiocin (100), paromomycin (10), spiramycin (50), and sulfamethoxazole (100) (Hamid et al., 2001b), and sensitive to (μg per disc) imipenem (2.5), but not to 5-fluorouracil (30), kanamycin (30), and tobramycin (10) (Kageyama et al., 2005d). Grows in the presence (%, w/v) of sodium nitrate (0.1), but does not grow in the presence of pyronin G (0.1), sodium azide (0.01), sodium chloride (7), tetrazolium salt (0.1), and thallous acetate (0.001). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:0}$, $C_{18:0}$, and *cis*11$C_{20:1}$, and traces of $C_{16:0}$ and $C_{20:0}$. Mycolic acids have 50–58 carbon atoms with 0–3 double bonds. Pyrolysis mass chromatography of purified mycolic acid methyl esters release fatty acid methyl esters ($C_{13:0}$–$C_{16:0}$). Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and those of corresponding strains of closely related species are as follows: (i) *Nocardia asteroides* (31%), *Nocardia nova* (29%), *Nocardia salmonicida* (31%), and *Nocardia seriolae* (18%) (Kudo et al., 1988), and (ii) *Nocardia tenerifensis* (15.2%) (Kämpfer et al., 2004).

DNA G+C content (mol%): 66–71 (T_m).

Type strain: ATCC 3318, CCUG 10109, CCUG 27778, CCUG 48656, CIP104775, DSM 43665, IEGM 621, IFO (now NBRC) 15532, JCM 3088, NCTC 11134, NRRL B-2089.

Sequence accession no. (16S rRNA gene): Z36936.

Additional remarks: Tsukamura (1982b) proposed the rejection of the name *Nocardia farcinica* as a *nomen dubium* as some strains bearing this name were members of the genus *Mycobacterium*. However, Chamoiseau (1979) previously established two species, *Mycobacterium senegalense* (Approved Lists 1980) and *Mycobacterium farcinogenes* (Approved Lists 1980), to accommodate the farcy-associated strains of mycobacteria thereby eliminating the source of confusion. Thereafter, the Judicial Commission voted to deny the action proposed by Tsukamura (Wayne, 1982). Additional phenotypic properties are cited in extensive numerical taxonomic studies (Goodfellow, 1971; Orchard and Goodfellow, 1980; Tsukamura, 1982a).

29. **Nocardia flavorosea** Chun, Seong, Bae, Lee, Kang, Goodfellow and Hah 1998, 904[VP] (synonym: "*Nocardia flavoronea*" Liu, Ruan and Yan 1983)

fla.vo.ro′se.a. L. adj. *flavus* yellow; L. fem. adj. *rosea* rose-colored; N.L. fem. adj. *flavorosea* yellow rose.

Slightly acid-fast actinomycete. Forms an extensive branched substrate mycelium which fragments *in situ* into coccoid to rod-shaped elements. An orange substrate mycelium carries white to pinkish aerial hyphae. Does not form diffusible pigments. Colony elevation is convex to irregular and colony margins are filamentous. Growth occurs at 25–50°C, but not at 10°C or 45°C. 2-Deoxythymidine-5′-*p*-nitrophenyl (*p*NP), *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Does not use L-phenylalanine or L-valine as simultaneous carbon and nitrogen sources. Sensitive (μg per Oxoid disc) to gentamicin (10), streptomycin (10), and tobramycin (10), but not to bacitracin (10 U) and penicillin (10) (Chun et al., 1998). Sensitive to (μg per disc) imipenem (2.5), kanamycin (5.0), and tobramycin (2.5), but not to 5-fluorouracil (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39.

Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl. Mycolic acids have 50–56 carbon atoms with between 2–4 double bonds. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and the corresponding strain of *Nocardia carnea*, a closely related species, in the range 2–5% (Chun et al., 1998).

Source (type strain): soil collected in Yunnan Province, China.

DNA G+C content (mol%): 64–72 (T_m).

Type strain: CCUG 46925, CIP 104511, DSM 44480, IFO (now NRBC) 14341, JCM 3332, NRRL B-16176.

Sequence accession no. (16S rRNA gene): Z46754.

30. **Nocardia fluminea** Maldonado, Hookey, Ward and Goodfellow 2001, 1619[VP] (Effective publication: Maldonado, Hookey, Ward and Goodfellow 2000, 371.)

flu.mi′ne.a.. L. fem. adj. *fluminea* of, in, or belonging to a river.

Acid–alcohol-fast actinomycetes. Form an extensive branched substrate mycelium which fragments into coccoid to rod-shaped elements. Brownish colonies bear sparse aerial hyphae and produce a brown diffusible pigment on glucose-yeast extract agar. Colony elevation is convex to irregular and margins are filamentous. Does not grow at 45°C. 2-Deoxythymidine-5′-*p*-nitrophenyl (*p*NP), *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Sensitive (μg/ml) to cephaloridine (16), demethylchlortetracycline (16), gentamicin (8), neomycin (8), rifampin (1), streptomycin (16), and tobramycin (1) (Maldonado et al., 2001). Sensitive to (μg per disc) imipenem (2.5) and tobramycin (2.5); moderately sensitive to kanamycin (10.0); resistant to 5-fluorouracil (30) (Kageyama et al., 2005d). Resistant to lysozyme. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid.

Source: soil collected adjacent to the River Thames at Medmenham, England.

DNA G+C content (mol%): not determined.

Type strain: CCUG 46120, CCUG 46296, CIP 107226, DSM 44489, JCM 11440, NBRC 100377, NCIMB 13759, S1.

Sequence accession no. (16S rRNA gene): AF277204.

31. **Nocardia gamkensis** LeRoes and Meyers 2007, 1[VP] (Effective publication: *Nocardia gamkensis* Le Roes and Meyers 2006, 294.)

gam.ken′sis. N.L. fem. adj. *gamkensis* pertaining to the River Gamka in South Africa.

Slightly acid–alcohol-fast actinomycete. Forms a light orange substrate mycelium that carries white aerial hyphae on Bennett's agar. Fragmentation into rod-shaped elements occurs after 5 d growth on agar media. Grows well on Bennett's and yeast extract-malt extract agars. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. The polar lipid pattern is typical of the genus, as is the presence of mycolic acids on one-dimensional thin-layer chromatography of whole-organism methanolysates. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia xishanensis*, a closely related species, is 10.35±3.15% (Le Roes and Meyers, 2006).

Source: a soil sample taken from the banks of the River Gamka in the Swartberg Nature Reserve, Western Cape Province, South Africa.

DNA G+C content (mol%): not determined.

Type strain: CZH20, DSM 44956, JCM 14299, NRRL B-24450.

Sequence accession no. (16S rRNA gene): DQ235272.

32. **Nocardia harenae** Seo and Lee 2006, 2206[VP]

ha.re′na.e L. gen. n. *harenae* of sand, referring to the isolation of the type strain from beach sand.

Slightly acid-fast actinomycete. Forms an extensively branched, reddish-orange substrate mycelium that fragments into irregular rod-shaped elements. Moderate amounts of white, fragmenting aerial hyphae are formed on oatmeal and inorganic salts-starch agars (ISP media 3 and 4), but aerial hyphae formation is only sparse on tryptic soy and yeast extract-malt extract (ISP medium 2) agars. Does not produce diffusible pigments. Grows at 10–40°C, but not at 45°C, and at pH 4.1–10.1. Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{18:0}$ iso, $C_{18:0}$, and 2-OH-$C_{14:0}$, and traces of other saturated, iso and anteiso-branched chain fatty acids. Menaquinone and polar lipid profiles are typical of the genus, as is the presence of mycolic acids in one-dimensional thin-layer-chromatography of whole-cell methanolysates.

Source (type strain): beach sand collected on the coast of Jeju Island, Republic of Korea.

DNA G+C content (mol%): 68.9 (HPLC).

Type strain: JCM 14548, KCCM 42317, NRRL, B-24459, WS-20.

Sequence accession no. (16S rRNA gene): DQ282122.

33. **Nocardia higoensis** Kageyama, Yazawa, Mukai, Kinoshita, Takata, Nishimura, Kroppenstedt and Mikami 2004f, 1930[VP]

hi.go.en′sis. N.L. fem. adj. *higoensis* pertaining to Higo, a traditional geographical name for Kumamoto Prefecture in Japan, the source of the type strain.

Partially acid-fast actinomycete. Forms an extensive branched substrate mycelium that fragments *in situ* into rod-shaped elements (0.6–0.8 × 0.9–2.1 μm). Orange to reddish orange substrate mycelium bears white to reddish white aerial hyphae. Colonies lacking aerial hyphae may be produced. Colonies 0.3–0.6 mm in diameter are formed on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Susceptible (μg per disc) to imipenem (2.5), kanamycin (5.0), and tobramycin (2.5), and is slightly susceptible to 5-fluorouracil (30) (Kageyama et al., 2004f). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, $C_{18:0}$, $C_{19:1}$ *cis*9, and $C_{20:1}$ *cis*11, and traces of $C_{15:0}$ and 10-methyl $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of representative *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia farcinica* (9%) and *Nocardia shimofusensis* (28%) (Kageyama et al., 2004f).

Source (type strain): a patient with lung nocardiosis.

DNA G+C content (mol%): 69 (HPLC)

Type strain: NBRC 100133, DSM 44732, IFM 10084, JCM 12121.

Sequence accession no. (16S rRNA gene): AB108778.

34. **Nocardia ignorata** Yassin, Rainey and Steiner 2001b, 2130[VP]

ig.no.ra′ta. L. fem. part. adj. *ignorata* unrecognized, unknown, pertaining to the fact that the type strain was mistakenly used as a member of the genus *Mycobacterium* in a mycobacterial quality control test.

Slightly acid–alcohol-fast actinomycete. Forms a well developed orange substrate mycelium that bears white aerial hyphae. At a late stage of growth hyphae fragment into rod-shaped elements. Grows at 22–45°C. Gelatin and proline are used as simultaneous carbon and nitrogen sources, but not acetamide, alanine, or serine. Susceptible (μg per disc) to imipenem (2.5), and tobramycin (2.5) but not to 5-fluorouracil (30) and kanamycin (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, $C_{20:1}$, $C_{22:0}$, $C_{22:1}$, $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{16:1}$ *cis*7, $C_{17:0}$, and $C_{18:1}$ *cis*9, and traces of $C_{14:0}$, $C_{15:0}$, $C_{19:0}$, and $C_{20:0}$. Mycolic acids have 46–57 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of purified fatty acid methyl esters release fatty acid methyl esters ($C_{16:0}$–$C_{18:0}$). Menaquinone and polar lipid profiles are typical of the genus. The DNA–DNA relatedness values between the type strain and the corresponding strain of *Nocardia salmonicida*, a closely related species, is 19.8% (Yassin et al., 2001b).

DNA G+C content (mol%): 68.1 (HPLC).

Type strain: CCUG 48296, DSM 44496, IMMIB R-1434, JCM 11764, NRRL B-24141.

Sequence accession no. (16S rRNA gene): AJ303008.

35. **Nocardia inohanensis** Kageyama, Yazawa, Nishimura and Mikami 2004i, 568g[VP]

in.o.han.en′sis. N.L. fem. adj. *inohanensis* of or pertaining to Inohana, Chiba, Japan, where the type strain was isolated.

Partially acid-fast actinomycete. Forms an extensively branched grayish tan to tan substrate mycelium which fragments into rod-shaped elements. Aerial hyphae are only visible microscopically. Short chains of spores are formed at the tips of aerial hyphae. Colonies are 0.3–1.3 mm in diameter on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Resistant (μg per disc) to impenem (10), kanamycin (30), and tobramycin (10) (Kageyama et al., 2004i). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia nugatensis* (10%), *Nocardia otitidiscaviarium* (7.7%), *Nocardia seriolae* (13%), *Nocardia uniformis* (17%), and *Nocardia yamanashiensis* (44%) (Kageyama et al., 2004i).

Source (type strain): clinical material in Mexico.

DNA G+C content (mol%): 68.8–69.5 (HPLC).

Type strain: DSM 44667, IFM 0092, JCM 11891, NBRC 100128.

Sequence accession no. (16S rRNA gene): AB092560.

36. **Nocardia iowensis** Lamm, Khare, Conville, Lau, Bergeron and Rosazza 2009, 2411[VP]

i.o.wen′sis. N.L. fem. adj. *iowensis* of or belonging to the State of Iowa, the source of the isolate.

Acid-fast actinomycete. Forms a substrate mycelium that fragments into irregular elements. A whitish substrate mycelium bears whitish aerial hyphae on sporulating agar after a few days at 29°C. Moderate growth occurs on asparagine-glucose, Benedict's, Bennett's potato starch, Weinstein's and yeast extract agars, light growth on Hickey and Tresner's, oatmeal and tomato paste agars, but poor growth on Czapek's, inorganic salts-starch, Kustner's oatflake and rice agars. Optimal growth temperature is 29°C. Additional phenotypic properties are cited in Table 39. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:1}$ *cis*8 and $C_{17:0}$,

and traces of $C_{10:0}$, $C_{14:0}$, $C_{15:1}$ *cis*5, $C_{17:0}$ 10-methyl, $C_{18:0}$, $C_{19:1}$ *cis*9, $C_{20:1}$ *cis*9, $C_{18:0}$ 10-methyl, and $C_{19:0}$ 10-methyl. Menaquinone and polar lipid profiles are typical of the genus, as is the presence of mycolic acids. DNA–DNA relatedness values of the type strain to corresponding strains of *Nocardia brasiliensis* and *Nocardia tenerefensis*, closely related species, are between 15.8 and 19.9% and between 5.4 and 7.4%, respectively (Lamm et al., 2009).

Source: a garden soil sample collected in Osceola, Iowa, USA.

DNA G+C content (mol%): not determined.

Type strain: DSM 45197, NRRL 5646, NRRL B-24671, UI 122540.

Sequence accession no. (16S rRNA gene): DQ925490.

Additional remarks: the taxonomic status of the species is supported by the results of 65-kDa heat-shock protein (*hsp 65*) and preprotein translocase (*secA1*) gene sequence analyses (Lamm et al., 2009). The type strain is a rich source of biotransforming enzymes and nitric oxide synthase.

37. **Nocardia jejuensis** Lee 2006, 561[VP]

je.ju.en′sis. N.L. fem. adj. *jejuensis* of or belonging to Jeju Island, Republic of Korea, from where the type strain was isolated.

Slightly acid–alcohol-fast actinomycete. Forms an extensive branched substrate mycelium that fragments into rod-shaped elements. An orange substrate mycelium carries a white to pinkish aerial mycelium which fragments into rod-shaped elements. Grows at 10–37°C, and at pH 4.1–10.1. Susceptible (μg per disc) to 5-fluorouracil (30) and tobramycin (2.5) and slightly susceptible to impenem (10) and kanamycin (30) (Hoshino et al., 2007). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{16:1}$, and $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus.

Source: a natural cave on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 69.6 (HPLC).

Type strain: JCM 13281, N3–2, NBRC 103114, NRRL B-24430.

Sequence accession no. (16S rRNA gene): AY964666.

38. **Nocardia jiangxiensis** Cui, Wang, Huang, Liu and Goodfellow 2005, 1924[VP]

jiang.xi.en′sis. N.L. fem. adj. *jiangxiensis* of or belonging to Jiangxi Province, southern China, the source of the type strain.

Partially acid–alcohol-fast actinomycete. Forms an extensive branched substrate mycelium that fragments into rod-shaped elements. A pinkish white to orange substrate mycelium bears sparse to abundant white to pink aerial hyphae on modified Sauton's agar. A yellowish brown substrate mycelium carries white aerial hyphae on oatmeal agar (ISP medium 3) at an initial pH of 5.5. Does not form diffusible pigments. Grows at 17–37°C, but not at 10 or 45°C, and at an initial pH of 3.5 and 9.5. L-Alanine-*p*-nitroanilide (*p*NA), *p*-nitrophenyl (*p*NP)-β-D-galactopyranoside, *p*NP-β-D-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, and *p*NP-β-D-xylopyranoside are hydrolyzed, but not 2-deoxythymidine-5′-*p*NP phosphate, *p*NP-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3 carbonyl *p*NA, *p*NP-phosphorylcholine, or L-proline *p*NA. Susceptible (μg per disc) to 5-fluorouracil (30) and impenem (2.5), and moderately susceptible to kanamycin (10) and tobramycin (5.0) (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:0}$, $C_{15:1}$ *cis*5, $C_{17:1}$ *cis*8, $C_{17:1}$ *cis*5, $C_{17:0}$, and traces of $C_{14:0}$, $C_{20:0}$, and $C_{16:1}$ *cis*9. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia miyunensis* (53%), *Nocardia nova* (46%), and *Nocardia pseudobrasiliensis* (39%) (Cui et al., 2005).

Source: the rhizosphere of goose grass (*Eleusine indica*) that was growing next to a copper mine in Wushan, Jiangxi Province.

DNA G+C content (mol%): not determined.

Type strain: 43401, CGMCC 4.1905, DSM 43401, JCM 12861, NBRC 101359.

Sequence accession no. (16S rRNA gene): AY639902.

39. **Nocardia jinanensis** Sun, Zhang, Huang, Zhang, Yang and Liu 2009, 419[VP]

ji.nan.en′sis. N.L. fem. adj. *jinanensis* of or pertaining to Jinan, capital city of Shandong Province, China, soil of which was the source of the type strain.

Partially acid–alcohol-fast actinomycete. Forms a branched substrate mycelium that fragments *in situ* into irregular rod-shaped elements. White to yellow substrate hyphae bear sparse to abundant, white to yellowish aerial hyphae on standard agar media such as yeast extract-malt extract agar (ISP medium 2). Does not produce diffusible pigments. Grows at 15–37°C and pH 5.5–10.5, but not at 45°C and pH 4.5. L-Phenylalanine is used as a simultaneous carbon and nitrogen source. Sensitive (μg per disc) to filter-paper soaked in kanamycin (30) and tobramycin (10). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, $C_{18:1}$ *cis*9, and $C_{15:0}$ iso 2-OH. Menaquinone and polar lipid profiles are characteristic of the genus, as is the presence of mycolic acids in whole-cell methanolysates. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia speluncae*, a closely related species, is 22.5±2.1% (Sun et al., 2009).

Source: a soil sample collected from Jinan City, Shandong Province, Northern China.

DNA G+C content (mol%): 65.0 (T_m).

Type strain: 04-5195, CGMCC 4.3508, DSM 45048, JCM 14879.

Sequence accession no. (16S rRNA gene): DQ 462650.

40. **Nocardia kruczakiae** Conville, Brown, Steigerwalt, Lee, Anderson, Fishbain, Holland and Witebsky 2005, 547[VP] (Effective publication: Conville, Brown, Steigerwalt, Lee, Anderson, Fishbain, Holland and Witebsky 2004, 5144.)

kruc.zak′e.i. N.L. gen. fem. n. *kruczakiae* of Kruczak, in memory of Patricia Kruczak-Filipov (1953–1997), in honor of and recognition for her contributions to the Mycology and Mycobacteriology Sections of the Microbiology Service, Department of Laboratory Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, USA.

Weakly acid-fast actinomycetes. Form a branched substrate mycelium that carries aerial hyphae. Grows at 25–45°C, with best growth at 45°C. Susceptible to amikacin, ceftriazone, clarithromycin, imipenem, linezolid, minocycline, and trimethoprim-sulfamethoxazole, but not to amoxicillin-clavulanic acid, ciprofloxacin, and sulfamethoxazole (Conville et al., 2004). Susceptible to (µg per disc) 5-fluorouracil (30) and impenem (2.5), moderately susceptible to kanamycin (10.0), but resistant to tobramycin (10) (Hoshino et al., 2007). DNA–DNA relatedness values between the type strain and the corresponding strains of closely related species are as follows: *Nocardia africana* (58±4.5%), *Nocardia nova* (60±5.5%), and *Nocardia veterana* (55±8.5%) (Conville et al., 2004).

Source: a respiratory pathogen isolated from immunocompromised patients.

DNA G+C content (mol%): not determined.

Type strain: ATCC BAA-948, DSM 44877, JCM 13022, MB2876, NBRC 101016.

Sequence accession no. (16S rRNA gene): AY441974.

41. **Nocardia lijiangensis** Xu, Li, Tang, Jiang, Gao, Xu and Jiang 2006b, 2025[VP] (Effective publication: *Nocardia lijiangensis* Xu, Li, Yang, Jiang, Gao, Xu and Jiang 2006a, 312.)

li.jiang.en′sis. N.L. fem. adj. *lijiangensis* of or pertaining to the city of Lijiang, in Yunnan Province, southwest China, the source of the type strain.

Slightly acid–alcohol-fast actinomycete which forms an extensively branched substrate mycelium which fragments into rod-shaped elements. Aerial hyphae fragment into short to elongated rod-like elements. Grows well on yeast extract-malt extract agar (ISP medium 2) forming a white aerial mycelium and a deep orange yellow substrate mycelium. A yellow white aerial mycelium and a light to pale yellow substrate mycelium is formed on oatmeal, inorganic salt-starch, and glycerol-asparagine agars (ISP media 3–5). Grows at 28–37°C and pH 7.0–9.0. Susceptible (µg per disc) to amikacin (30), aureomycin (30), chloramphenicol (30), erythromycin (15), gentamicin (10), netilimicin (10), streptomycin (10), terramycin (30), tetracycline (30), and tobramycin (10) but not to ciprofloxacin (10), kanamycin (10), novobiocin (30), oleandomycin (10), penicillin-G (10 U), polymyxin B (300 U), and vancomycin (10) (Xu et al., 2006a). Susceptible (µg per disc) to impenem (2.5) and tobramycin (2.5) but not to 5-fluorouracil (10) and kanamycin (30) (Hoshino et al., 2007). Resistant to lysozyme. Grows in the presence of phenol (0.01%, w/v) but not of sodium chloride. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and lesser proportions of $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{16:1}$ *cis*7, iso- $C_{15:0}$ 2-OH, $C_{17:0}$ anteiso, $C_{18:2}$ *cis*6–9, and $C_{20:2}$ *cis*6–9. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia polyresistens* (45.4%) and *Nocardia xishanensis* (28.6%) (Xu et al., 2006a).

Source (type strain): soil collected in Lijiang, Yunnan Province, Southwest China.

DNA G+C content (mol%): 65.4 (T_m).

Type strain: CCTCC AA 204005, DSM 44933, JCM 13592, KCTC 19028, YIM 33378.

Sequence accession no. (16S rRNA gene): AY779043.

Additional remarks: the culture collection number DSM 44933 was provided on request for validation (Lists Editor, 2006b).

42. **Nocardia mexicana** Rodríguez-Nava, Couble, Molinard, Sandoval, Boiron and Laurent 2006, 925[VP] (Effective publication: *Nocardia mexicana* Rodriguez-Nava, Couble, Molinard, Sandoval, Boiron and Laurent 2004, 4534.)

me.xi.ca′na. N.L. fem. adj. *mexicana* of or belonging to Mexico City, the geographical area from which the isolates were collected.

Acid–alcohol-fast actinomycete. Forms extensively branched hyphae with a tendency to fragment in early stages of growth. Rough brownish purple colonies 1–3 mm in diameter are formed on Bennett's agar. Grows at 25–37°C, but not at 45°C. Susceptible (median inhibitory concentrations (µg/ml)) to amikacin (32), amoxycillin (>128), cefotaxime (8), ceftriaxone (3), ciprofloxacin (2), gentamicin (128), imipenem (16), sulfamethoxazole (128), trimethoprim-sulfamethoxazole (3.2/64), and tetracycline (64) (Rodriguez-Nava et al., 2004). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, $C_{18:1}$, and $C_{18:0}$, smaller proportions (<10%) of $C_{13:1}$, $C_{14:0}$, $C_{15:1}$, and $C_{17:1}$, and traces of $C_{15:0}$. Mycolic acids have 54–60 carbon atoms with C56 as the major component. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia asteroides* (26.3%) and *Nocardia pseudobrasiliensis* (32.1%) (Rodriguez-Nava et al., 2004).

Source: human mycetomas.

DNA G+C content (mol%): not determined.

Type strain: CIP 108295, DSM 44952, JCM 14590, OFN 1325.

Sequence accession no. (16S rRNA gene): AY903610.

Additional remarks: the culture collection accession number DSM 44952 was provided on request for validation (Lists Editor, 2006a).

43. **Nocardia miyunensis** Cui, Wang, Huang, Liu and Goodfellow 2005, 1924[VP]

mi.yun.en′sis. N.L. fem. adj. *miyunensis* of or belonging to Miyun County in Beijing, the source of the type strain.

Partially acid–alcohol-fast actinomycete which produces an extensively branched substrate mycelium that fragments into rod-shaped elements. A white to yellowish white substrate mycelium bears sparse to abundant, white to pink aerial hyphae on modified Sauton's agar. A yellowish-brown substrate mycelium carries white aerial hyphae on oatmeal agar (ISP medium 3) at an initial pH of 5.5. Does not form diffusible pigments. Grows at 17–37°C, but not at 10 or 45°C. Growth occurs at initial pH 4.5–9.5. Does not hydrolyze L-alanine (*p*NA), 2-deoxythymidine-5′ *p*-nitrophenyl (*p*NP) phosphate, *p*NP-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3-carbonyl *p*NA, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, L-proline *p*NA, or *p*NP-β-D-xylopyranoside. Susceptible (μg per disc) to 5-fluorouracil (30), impenem (2.5), kanamycin (5.0), and tobramycin (2.5) (Hoshino et al., 2007). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{18:1}$ *cis*9 and $C_{18:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia jiangiensis* (58%), *Nocardia nova* (54%), and *Nocardia pseudobrasiliensis* (42%) (Cui et al., 2005).

Source (type strain): a pine forest soil sample collected in Miyun County, Beijing, China.

DNA G+C content (mol%): not determined.

Type strain: 117, CGMCC 4.1904, DSM 17685, JCM 12860.

Sequence accession no. (16S rRNA gene): AY639901.

44. **Nocardia neocaledoniensis** Saintpierre-Bonaccio, Maldonado, Amir, Pineau and Goodfellow 2004, 602[VP]

ne.o.ca.le.do.ni.en′sis. N.L. fem. adj. *neocaledoniensis* of or pertaining to New Caledonia, the source of the isolate.

Slightly acid–alcohol-fast actinomycete. Forms an extensively branched substrate mycelium that fragments *in situ* into irregular rod-shaped elements. An orange substrate mycelium bears abundant pale orange aerial hyphae on modified Bennett's agar. Melanin pigments are produced on peptone-yeast extract-iron agar (ISP medium 6). Grows at 10–45°C and pH 4–12. Sensitive (μg/ml) to tetracycline (30) but not to erythromycin (4), gentamicin (10), penicillin G (25), rifamipicin (6), streptomycin (5), and vancomycin (10) (Saintpierre-Bonaccio et al., 2004). Sensitive to (μg per disc) impenem (2.5) and tobramycin (2.5), slightly susceptible to kanamycin (30) and weakly susceptible to 5-fluorouracil (30) (Hoshino et al., 2007). Grows in the presence (%, w/v) of crystal violet (0.0002), phenol (0.01), and sodium chloride (3) but not in the presence of potassium tellurite (0.005) and sodium chloride (5). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia asteroides*, a closely related species, is 40.8% (Saintpierre-Bonaccio et al., 2004).

Source (type strain): a brown hypermagnesian ultramafic soil at the Southern end of the main island of New Caledonia.

DNA G+C content (mol%): not determined.

Type strain: DSM 44717, JCM 12604, NCIMB 13955, SBH_R OA6.

Sequence accession no. (16S rRNA gene): AY282603.

45. **Nocardia niigatensis** Kageyama, Yazawa, Nishimura and Mikami 2004i, 568[VP]

ni.i.gat.en′sis. N.L. fem. adj. *niigatensis* of or pertaining to Niigata, Japan, the source of the isolate.

Partially acid-fast actinomycete. Forms branched substrate hyphae that fragment into oval to rod-shaped elements. Tan to grayish-tan colonies bear sparse, white, patchy distributed aerial hyphae. Short chains of spores may occur on the aerial mycelium. A faint brown diffusible pigment is produced. Colonies 1.5–3.2 mm in diameter are produced on Mueller–Hinton medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. L-Alanine *p*-nitroanilide (*p*NA), 2-deoxythymidine-5′ *p*-nitrophenyl (*p*NP), *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, and *p*NP-xylopyranoside are hydrolyzed, but not *p*NP-α-D-galactopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-carboxyl *p*NA, *p*NP-phosphorylcholine, or L-proline *p*NA. Susceptible (μg per disc) to tobramycin (2.5) and kanamycin (5), but not to impenem (10) (Kageyama et al., 2004i). Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and/or $C_{16:1}$ *cis*7/$C_{15:0}$ iso 2-OH and $C_{18:0}$ 10-methyl; smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:0}$, $C_{18:0}$, $C_{15:1}$ *cis*5, $C_{17:1}$ *cis*8, and $C_{17:0}$ 10-methyl, and traces of $C_{16:0}$ 10-methyl. Muramic acid moieties are *N*-glycolated. Mycolic acids co-migrate on one-dimensional thin-layer chromatography with those of whole-organism methanolysates of representative *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia inohanensis* (21%), *Nocardia otitidiscaviarum* (20%), *Nocardia*

seriolae (41%), *Nocardia uniformis* (22%), and *Nocardia yamanashiensis* (29%) (Kageyama et al., 2004i).

Source: skin abscesses.

DNA G+C content (mol%): 68.8–69.5 (HPLC).

Type strain: DSM 44670, IFM 0330, JCM 11894, NBRC 100131.

Sequence accession no. (16S rRNA gene): DQ659910.

46. **Nocardia ninae** Laurent, Rodríguez-Nava, Noussair, Couble, Nicolas-Chanoine and Boiron 2007, 664[VP]

ni′na.e. N.L. fem. gen. n. *ninae* of Nina, the first name of the patient from whom the type strain was isolated.

Acid–alcohol-fast actinomycete. Produces branched hyphae which tend to fragment into coccoid and rod-like elements. An orange substrate mycelium bears sparse to moderate amounts of white aerial hyphae. Rough colonies 1–3 mm in diameter are formed on Bennett's agar. Grows at 37°C, but not at 45°C. Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain *meso*-diaminopimelic acid as the only peptidoglycan diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$, and $C_{18:0}$ 10-methyl, and a smaller proportions (<10%) of $C_{18:0}$. Mycolic acids have 52–58 carbon atoms. The menaquinone profile is typical of the genus. The DNA–DNA relatedness values between the type strain and the corresponding strain of *Nocardia alba*, a closely related species, is below 20% (Laurent et al., 2007). These workers were also able to separate the type strain from corresponding strains of other *Nocardia* species, including *Nocardia alba* and *Nocardia jejuensis*, on the basis of *hsp65* gene sequences.

Source: a human respiratory sample.

DNA G+C content (mol%): not determined.

Type strain: CIP 108955, DSM 44978, JCM 14667, OFN 02.72.

Sequence accession no. (16S rRNA gene): DQ235687.

47. **Nocardia nova** Tsukamura 1983, 896[VP] (Effective publication: Tsukamura 1982a, 1115.)

no′va. L. fem. adj. *nova* new.

Weakly or partially acid-fast actinomycete. Forms a mycelium that fragments into coccoid and rod-shaped elements. Forms rough orange colonies. Grows at 28–42°C, but not at 45°C. L-Alanine-*p*-nitroanilide (*p*NA), *p*-nitrophenyl-α-D-glucopyranoside, (*p*NP)-β-D-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, and *p*NP-xylopyranoside are hydrolyzed, but not deoxythymidine-5′-*p*NP-phosphate, *p*NP-α-D-galactopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3-carboxyl *p*NA, *p*NP-phosphorylcholine, or L-proline, *p*NA. Does not use acetamide, L-alanine, gelatin, proline, or serine as simultaneous carbon and nitrogen sources. The type strain is sensitive (μg/ml) to kanamycin (5), lincomycin (10), novobiocin (10), paromomycin (100), polymyxin (5), spiramycin (5), and sulfamethoxazole (10) but resistant to ampicillin (5), cephaloridine (100), erythromycin (10), gentamicin (10), kanamycin (50), lividomycin (10), neomycin (10), novobiocin (100), penicillin (10), polymyxin (50), spiramycin (50), and streptomycin (10) (Hamid et al., 2001b). Sensitive to (μg per disc) imipenem (2.5) and 5-fluorouracil (30) but not to kanamycin (30) and tobramycin (10) (Kageyama et al., 2005d). Grows in the presence (%, w/v) of pyronin G (0.1) but not in the presence of sodium azide (0.01), sodium chloride (7), sodium nitrate (0.1), tetrazolium salt (0.1), and thallous acetate (0.001). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and/or $C_{16:1}$ *cis*7/$C_{15:0}$ iso 2-OH and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:0}$, and $C_{18:0}$. Mycolic acids contain 52–64 carbon atoms with 1–4 double bonds, including one in the α-alkyl position. DNA–DNA relatedness values between the type strain and the corresponding strains of closely related species are as follows: (i) *Nocardia asteroides* (19%), *Nocardia farcinica* (16%), *Nocardia salmonicida* (24%), and *Nocardia seriolae* (8%) (Kudo et al., 1988); (ii) *Nocardia asteroides* (39%) and *Nocardia farcinica* (20%) (Yano et al., 1990); (iii) *Nocardia abscessus* (9%), *Nocardia asteroides* (14%), *Nocardia paucivorans* (11%), *Nocardia pseudobrasiliensis* (16%), *Nocardia transvalensis* (23%), *Nocardia vaccinii* (16%), and *Nocardia vinacea* (9%) (Kinoshita et al., 2001); (iv) *Nocardia africana* (3%), *Nocardia cerradoensis* (11%), *Nocardia vaccinii* (13%), *Nocardia vermiculata* (10%), *Nocardia veterana* (12%), and *Nocardia vinacea* (3%) (Kageyama et al., 2004c).

Source: sputa of patients with lung disease.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33726, CCUG 45939, CIP 104777, DSM 44481, R.E. Gordon R443, IFO (now NBRC) 15556, JCM 6044, VKM Ac-1971, Tsukamura 23095.

Sequence accession no. (16S rRNA gene): AF430028.

48. **Nocardia otitidiscaviarum** corrig. Snijders 1924, 338[AL] ["*Actinomyces caviae*" Erikson 1935; *Nocardia caviae* (Erikson 1935) Erikson 1935]

o.ti.ti.dis.ca.vi.a′rum. N.L. n. *otitis*, *-idis* inflammation of the ear; N.L. n. *Cavia* (gen. plur. *caviarum*) generic name for cavy, another name for guinea pig; N.L. gen. pl. n. *otitidiscaviarium* of ear disease of guinea pigs.

Weakly acid–alcohol-fast actinomycete. Forms an extensively branched substrate mycelium which fragment into coccoid to rod-shaped elements. Cream grayish to peach tan to purplish substrate hyphae carry very sparse, off-white aerial hyphae. The latter are always present but may only be visible microscopically. Soluble pigments variably present. Grows at 30–45°C. 2-Deoxythymidine-5′ *p*-nitrophenyl (*p*NP), *p*NP-phosphorylcholine, and *p*NP-β-D- xyloside are hydrolyzed. L-Alanine and serine are used as simultaneous carbon and nitrogen sources, but not acetamide, gelatin, or proline. Susceptible to amikacin, chloramphenicol, clindamycin, gentamicin, kanamycin, and minocycline but not to ampicillin, amoxicillin-clavulanic acid, perfloxacin, trimethoprim, trimethoprin-sulfamethoxazole; variable responses to cefotaxime, cefuroxime, and tetracycline (Boiron and Provost, 1988b). The type strain is sensitive (μg/ml) to amoxicillin (10), ampicillin (50), bacitracin (10), cephaloridine (100), erythromycin (10), gentamicin (10), kanamycin (5), lincomycin (10), lividomycin (10), neomycin (100), penicillin (100), polymyxin (50), streptomycin (100), and sulfamethoxazole 100, but resistant to ampicillin (100), deoxycycline (10), erythromycin (100),

novobiocin (10), and spiramycin (50) (Hamid et al., 2001b). Sensitive to (µg per disc) kanamycin (5.0); slightly susceptible to tobramycin (10.0), but resistant to 5-fluorouracil (30) and imipenem (10) (Kageyama et al., 2005d). Grows in the presence (%, w/v) of sodium chloride (5), sodium nitrate (0.1) but not in the presence of pyronin G (0.1), sodium azide (0.01), sodium chloride (7), tetrazolium salt (0.1), and thallous acetate (0.001). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions $C_{16:1}$ *cis*9, $C_{16:0}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{5:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, 10-methyl-$C_{17:0}$, $C_{18:1}$ *cis*9, $C_{19:1}$ *cis*9, and 10-methyl-$C_{19:0}$, and traces of $C_{14:0}$ and $C_{15:1}$ *cis*10. Mycolic acids have 40–60 carbon atoms with 0–3 double bonds. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty and methyl esters ($C_{12:0}$–$C_{18:0}$). Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia inohanensis* (23%), *Nocardia niigatensis* (20%), *Nocardia seriolae* (19%), *Nocardia uniformis* (19%), and *Nocardia yamanashiensis* (25%) (Kageyama et al., 2004i).

Source: soil, but some strains are pathogenic for animals, including humans.

DNA G+C content (mol%): 66–67 (T_m).

Type strain: ATCC 14629, CCUG 10075, CIP 104514, DSM 43242, IFO (now NBRC) 14405, JCM 3377, JCM 3393, NCTC 1934, VKM Ac-869.

Sequence accession no. (16S rRNA gene): AF430067.

Additional remarks: the original spelling, namely *Nocardia otidis-caviarum* (*sic*), was corrected by Farmer (1983) and Hill et al. (1984). Additional phenotypic properties are cited in extensive numerical taxonomic studies (Goodfellow, 1971; Tsukamura, 1982a).

49. **Nocardia paucivorans** Yassin, Rainey, Burghardt, Brzezinka, Mauch and Schaal 2000a, 807[VP]

pau.ci.vo′rans. L. adj. *paucus* little; L. v. *vorare* to eat, to devour; L. pres. part. *vorans* eating; N.L. part. adj. *paucivorans*, eating little, referring to the few compounds that are utilized as sole sources of carbon and energy.

Slightly acid–alcohol-fast actinomycete. Forms a well developed substrate mycelium that penetrates agar media and bears white aerial hyphae. At a late stage of growth, hyphae fragment into rod-shaped elements. Does not hydrolyze 2-deoxythymidine-5′-*p*-nitrophenyl (*p*NP) phosphate, *p*NP-phosphorylcholine, or *p*NP-β-xyloside. Does not use acetamide, alanine, gelatin, proline, or serine as simultaneous carbon and nitrogen sources. Susceptible (µg per disc) to imipenem (2.5), kanamycin (5.0), and tobramycin (2.5) but not to 5-fluorouracil (30) (Kageyama et al., 2005d). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:1}$ *cis*9 and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{15:0}$, $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$. Mycolic acids have 48–54 carbon atoms with 2–4 double bonds. Pyrolysis gas chromatography of mycolic acids methyl esters release fatty acid methyl esters ($C_{14:0}$–$C_{18:0}$) with $C_{16:0}$ as the major component. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and the corresponding strains of related species are as follows: (i) *Nocardia brevicatena* (61.9%) (Yassin et al., 2001a), and (ii) *Nocardia abscessus* (5%), *Nocardia asteroides* (7%), *Nocardia nova* (6%), *Nocardia pseudobrasiliensis* (6%), *Nocardia transvalensis* (6%), *Nocardia vaccinii* (6%), and *Nocardia vinacea* (4%) (Kinoshita et al., 2001).

Source (type strain): sputa and bronchial secretions of a patient with chronic lung disease.

DNA G+C content (mol%): 65.9 (HPLC).

Type strain: ATCC BAA-278, CCUG 46117, CIP 10698, DSM 44386, IMMIB D-1632, JCM 10919, NBRC 100373.

Sequence accession no. (16S rRNA gene): AF430041.

50. **Nocardia pigrifrangens** Wang, Zhang, Huang, Maldonado, Liu and Goodfellow 2004, 1685[VP]

pi.gri.frang′ens. L. adj. *piger* slow; L. part. adj. *frangens* (from L. v. *frango*) breaking up, small; N.L. part. adj. *pigrifrangens* slow to break up, referring to the fact that the substrate mycelium remains stable for up to 14 d before undergoing fragmentation.

Slightly acid–alcohol-fast actinomycete. Forms a branched substrate mycelium that fragments *in situ* into rod-shaped elements. An orange substrate mycelium bears sparse white to pinkish aerial hyphae on modified Bennett's, modified Sauton's, and oatmeal agars. Colonies are convex with filamentous margins. Grows at 18–35°C, but not at 45°C. L-Alanine, L-aspartate, L-glutamate, monoethanolamine, L-proline, uric acid, and L-valine are used as simultaneous carbon and nitrogen sources, but not acetamide, gelatin, L-leucine, L-phenylalanine, or urea. Susceptible (µg per disc) to 5-fluorouracil (30), impenem (2.5), kanamycin (5.0), and tobramycin (2.5) (Hoshino et al., 2007). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{16:1}$ *cis*7 and *cis*9-$C_{21:1}$. Menaquinone and polar lipid profiles are typical of the genus.

Source (type strain): a contaminated plate of a clinically significant strain in Shanghai, China.

DNA G+C content (mol%): 68.7 (T_m).

Type strain: 7031, AS 4.1808, DSM 44957, JCM 11884.

Sequence accession no. (16S rRNA gene): AF219974.

51. **Nocardia pneumoniae** Kageyama, Yazawa, Mukai, Kohara, Nishimura, Kroppenstedt and Mikami 2004g, 2028[VP]

pneu.mo.ni′a.e. Gr. fem n. *pneumonia* disease of the lungs; N.L. fem. n. *pneumonia* disease of the lungs N.L. gen. n. *pneumoniae* of a disease of the lungs, of pneumonia.

Partially acid–alcohol-fast actinomycete. Forms a branched substrate mycelium that fragments into rod-shaped elements (0.3–0.5 × 0.6–1.1 µm). A faint yellow substrate mycelium bears white to grayish white hyphae. Does not produce soluble pigments. Colonies 2.0–3.0 mm

in diameter are formed on Mueller–Hinton II medium supplemented with glucose (0.2 mm) after 7 d at 30°C. Grows at 37 and 45°C. Susceptible (μg per disc) to impenem (2.5) and slightly susceptible to kanamycin (Kageyama et al., 2004g). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*7, $C_{19:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{18:0}$ and $C_{19:1}$ *cis*, and traces of $C_{15:0}$, $C_{16:1}$ *cis*9, $C_{16:1}$ *cis*8, $C_{16:0}$ 10-methyl, $C_{17:1}$ *cis*9, 10-methyl-$C_{17:0}$, $C_{19:1}$ *cis*11, and $C_{19:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and the corresponding strains of related species are as follows: *Nocardia araonensis* (35%) and *Nocardia beijingensis* (<46%) (Kageyama et al., 2004g).

Source (type strain): a patient with a history of lung cancer, emphysema, and radiation pneumonia.

DNA G+C content (mol%): 68 (HPLC).

Type strain: DSM 44730, IFM 0784, JCM 12119, NBRC 100136.

Sequence accession no. (16S rRNA gene): AB108780.

52. **Nocardia polyresistens** Xu, Li, Tang, Jiang, Chen, Xu and Jiang 2005, 1469[VP]

po.ly.re.sis′tens. Gr. adj. *polus* many; L. part. adj. *resistens* resisting; N.L. part. adj. *polyresistens* resisting many (antibiotics).

Slightly acid–alcohol-fast actinomycete. Forms extensively branched aerial and substrate hyphae that fragment into irregular rod-shaped elements. A pale-yellow to moderate orange-yellow substrate mycelium bears sparse to abundant, white aerial hyphae on modified Bennett's. Czapek's, nutrient, potato, modified Sauton's, and yeast extract-malt extract agars. A pale yellow to yellow-white substrate mycelium carries pale yellow to yellow-white aerial hyphae on inorganic salts-starch and glycerol-asparagine agars (ISP media 4 and 5). Does not form diffusible pigments. Grows at 28–37°C, but not at 45°C, and grows at pH 7–9. L-Asparagine, L-histidine, and L-tyrosine are used as sole nitrogen sources, but not acetamide, L-arginine, L-cysteine, L-glutamic acid, glycine, L-hydroxyproline, L-lysine, L-methionine, or L-threonine. Susceptible (μg per disc) to chloramphenicol (30), streptomycin (10), and tetracycline (30) but not to amikacin (30), aureomycin (30), ciprofloxacin (10), erythromycin (15), gentamicin (10), kanamycin (5), netilimicin (10), novobiocin (30), oleandomycin (10), penicillin G (10 U), polymycin-B (300 U), terramycin (30), tobramycin (10) and vancomycin (10) (Xu et al., 2005). Susceptible (μg per disc) to impenem (2.5) and tobramycin 2.5 but not to 5-fluorouracil (30) and kanamycin (30) (Hoshino et al., 2007). Resistant to lysozyme. Grows in the presence (%, w/v) of phenol (0.1) but not in the presence of sodium chloride (4). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:2}$ *cis*6–9, $C_{18:1}$ *cis*9, $C_{18:0}$, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{16:1}$ *cis*7, $C_{15:0}$ iso 2-OH, $C_{17:0}$, $C_{17:0}$ anteiso, and $C_{17:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus.

Source: soil collected in Yunnan Province, southwest China.

DNA G+C content (mol%): 65.6 (T_m).

Type strain: CCTCC AA 204004, JCM 13593, KCTC 19027, YIM 33361.

Sequence accession no. (16S rRNA gene): AY626158.

53. **Nocardia pseudobrasiliensis** Ruimy, Riegel, Carlotti, Boiron, Bernardin, Monteil, Wallace and Christen 1996, 263[VP]

pseu.do.bra.si.li.en′sis. Gr. adj. *pseudês* false; N.L. fem. adj. *brasiliensis* a specific epithet; N.L. fem. adj. *pseudobrasiliensis* a false (*Nocardia*) *brasiliensis*.

Acid-fast to partially acid-fast actinomycete. Forms a branched substrate mycelium that fragments into bacteroid, coccoid or rod-shaped elements. An aerial mycelium is produced. Grows at 30–37°C, but not at 10 or 45°C. L-Alanine-*p*-nitroanilide (*p*NA), *p*-nitrophenyl (*p*NP)-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, and *p*NP-β-D-xylopyranoside are hydrolyzed, but not 2-deoxythymidine-5′-*p*NP- phosphate, *p*NP-β-D-glucuronide, L-glutamate-γ-3-carboxyl *p*NA, *p*NP-phosphorylcholine, or L-proline *p*NA. Susceptible (μg per disc) to imipenem (2.5), tobramycin (2.5) but not to 5-fluorouracil (30) and kanamycin (30) (Kageyama et al., 2005d). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ and/or $C_{16:1}$ *cis*7/$C_{15:0}$ iso 2-OH, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{17:0}$, $C_{18:0}$, and $C_{18:1}$ *cis*9, and traces of $C_{14:0}$, $C_{17:1}$ *cis*8, and $C_{17:0}$ 10-methyl. The menaquinone profile is typical of the genus, as is the presence of mycolic acids in whole-organism methanolysates. DNA–DNA relatedness values between the type strain and the corresponding strains of related *Nocardia* species are as follows: (i) *Nocardia brasiliensis* (11%), *Nocardia nova* (12%), *Nocardia otitidiscaviarum* (11%), *Nocardia seriolae* (7%), and *Nocardia vaccinii* (14%) (Ruimy et al., 1996), and (ii) *Nocardia abscessus* (7%), *Nocardia asteroides* (12%), *Nocardia nova* (13%), *Nocardia paucivorans* (8%), *Nocardia transvalensis* (17%), *Nocardia vaccinii* (13%), and *Nocardia vinacea* (9%) (Kinoshita et al., 2001).

Source (type strain): a leg abscess on a patient with ulcerative colitis.

DNA G+C content (mol%): 67–68 (chemical method).

Type strain: ATCC 51512, CCUG 35436, CIP 104600, DSM 44290, JCM 9894.

Sequence accession no. (16S rRNA gene): AF430042.

54. **Nocardia pseudovaccinii** Kim, Roth, Andrees, Lee and Kroppenstedt 2002b, 1828[VP]

pseu.do.vac.cin′i.i. Gr. adj. *pseudês* false; N.L. gen. n. *vaccinii* a specific epithet; N.L. gen. n. *pseudovaccinii* a false (*Nocardia*)

vaccinii, referring to the earlier misclassification of the type strain as a strain of *Nocardia vaccinii*.

A beige red substrate mycelium bears sparse white, branched aerial hyphae. The reverse side of the colony is yellow orange on yeast extract-malt extract agar. Deoxythymidine-5-*p*-nitrophenyl (*p*NP) phosphate, *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Susceptible (μg per disc) to 5-fluorouracil (30), impenem (2.5), and tobramycin (2.5) but not to kanamycin (30) (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acid moieties are *N*-glycolated. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$, $C_{18:1}$, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{17:1}$, $C_{17:0}$, 10-methyl-$C_{17:0}$, $C_{18:0}$, and $C_{19:1}$, and a trace of $C_{15:0}$. Mycolic acids have 50–58 carbons with C52, C54, and C56 as major components. Menaquinone and polar lipid profiles are typical of the genus.

Source: unknown.

DNA G+C content (mol%): not determined.

Type strain: AR 368,38366-20, DSM 43406, JCM 11883, NBRC 100343, NRRL B-24154.

Sequence accession no. (16S rRNA gene): AF430046.

Additional remarks: the name *Nocardia pseudovaccinii* Kim et al. 2002b was proposed for strain DSM 43406 which had previously been classified as *Nocardia vaccinii*.

55. **Nocardia puris** Yassin, Sträubler, Schumann and Schaal 2003, 1598[VP]

pu′ris. L. gen. n. *puris* of corrupt matter, pus, pertaining to the abscess from which the type strain was isolated.

Partially acid–alcohol-fast actinomycete. Forms a well developed irregularly branched substrate mycelium which bears white aerial hyphae. At a late stage in the growth cycle, hyphae fragment into rod-shaped elements. Grows at 22–45°C. Alanine is used as a simultaneous carbon and nitrogen source, but not acetamide, arginine, gelatin, ornithine, proline, or serine. Susceptible (μg per disc) to imipenem (2.5), tobramycin (10) but not to 5-fluorouracil (30) and kanamycin (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:0}$, $C_{18:1}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{16:1}$ *cis*7, $C_{17:0}$, $C_{20:0}$, $C_{20:1}$, $C_{21:0}$, and $C_{21:0}$, $C_{21:1}$, and traces of $C_{14:0}$, $C_{15:0}$, $C_{19:0}$, $C_{20:0}$, and $C_{21:0}$. Pyrolysis gas chromatography of purified mycolic acid methyl esters release fatty acid methyl esters ($C_{14.0}$–$C_{18:0}$) with $C_{16:0}$ as the major component. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA reassociation values between the type strain and corresponding strains of related species are as follows: *Nocardia abscessus* (20.6%), *Nocardia cyriacigeorgica* (37.6%), and *Nocardia farcinica* (42.3%) (Yassin et al., 2003).

Source (type strain): a human abscess.

DNA G+C content (mol%): not determined.

Type strain: CCUG 48752, DSM 44599, JCM 13031, IMMIB R-145, NRRL B-24204.

Sequence accession no. (16S rRNA gene): AJ508748.

56. **Nocardia salmonicida** (*ex* Rucker) Isik, Chun, Hah and Goodfellow 1999b, 834[VP]

sal.mo.ni′ci.da. L. n. *salmo, salmonis* salmon; L. suff. *cida* from L. v. *caedo* to cut or kill; N.L. n. *salmonicida* salmon-killer ("*Streptomyces salmonicida*" Rucker 1949, "*Nocardia salmonicida*" (Rucker 1949) Pridham 1970.

Acid–alcohol-fast actinomycete. Forms an extensive branched substrate mycelium that fragments *in situ* into coccoid to rod-shaped elements. An orange substrate mycelium bears white to pink aerial hyphae on glucose-yeast extract agar. Does not form diffusible pigments. Colony elevation is convex to irregular and colony margins are filamentous. Grows at 20 and 30°C, but not at 10 or 45°C. *p*-Nitroanilide (*p*NP)-β-D-xyloside is hydrolyzed, but not 2-deoxythymidine-5′-(*p*NP) phosphate, or *p*-nitrophenyl (*p*NP-) phosphorylcholine. Proline and serine are used as simultaneous carbon and nitrogen sources, but not acetamide, L-alanine, or gelatin. Susceptible (μg per disc) to imipenem (2.5) and tobramycin (2.5); slightly susceptible to kanamycin (30.0), but resistant to 5-fluorouracil (30) (Kageyama et al., 2005d). Resistant to lysozyme. Growth occurs in the presence (%, w/v) of bismuth citrate (0.0001), crystal violet (0.0,0001), phenol (0.01), and sodium chloride (3) but not in the presence of sodium azide (0.01) and sodium chloride (10). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acid moieties are *N*-glycolated. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$, and $C_{18:0}$ 10-methyl. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of representative *Nocardia* strains and have 46–60 carbon atoms. The menaquinone profile is typical of the genus.

Source (type strain): diseased blueback salmon fingerlings (*Oncorhychus nerka*).

DNA G+C content (mol%): 66–67.0 (T_m).

Type strain: ATCC 27463, CBS 694.72, CIP 104517, DSM 40472, IFO (now NBRC) 13393, ISP 5472, JCM 4826, NRRL B-2778, NRRL B-12385.

Sequence accession no. (16S rRNA gene): AF430050.

57. **Nocardia seriolae** Kudo, Hatai and Seino 1988, 173[VP]

se.ri.o′ la.e. N.L. gen. n. *seriolae* of Seriola, named after *Seriola*, the genus of yellowtail fish from which the organism was isolated.

Branching substrate hyphae fragment into rod-like elements. Some strains form microscopically visible aerial hyphae. The substrate mycelium is yellowish-orange on yeast extract-malt extract agar (ISP medium 2). Grows at 15 and 30°C, but not above 35°C. *p*-Nitrophenyl (*p*NP)-β-D-xyloside is hydrolyzed, but not 2-deoxythymidine-5-*p*NP phosphate, or *p*NP-phosphorylcholine. Susceptible (μg per disc) to kanamycin (5.0) and tobramycin (2.5) but not to 5-fluorouracil (30) and imipenem (10) (Kageyama et al., 2005d). Grows in the presence of 5%, w/v sodium chloride. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$, $C_{18:1}$, and 10-methyl-$C_{19:0}$, smaller

proportions (<10%) of $C_{15:0}$, $C_{15:1}$, $C_{17:0}$, $C_{17:1}$, $C_{19:1}$, and 10-methyl-$C_{19:0}$, and traces of $C_{14:0}$, $C_{18:0}$, $C_{19:1}$, and 10-methyl-$C_{17:0}$. Mycolic acids have 44–58 carbon atoms and include odd numbered components. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: (1) *Nocardia asteroides* (37%), *Nocardia farcinica* (18%), and *Nocardia nova* (17%) (Kudo et al., 1988), and (ii) *Nocardia inohanensis* (33%), *Nocardia niigatensis* (42%), *Nocardia otitidiscaviarum* (14%), *Nocardia uniformis* (16%), and *Nocardia yamanashiensis* (29%) (Kageyama et al., 2004i).

Source: the causal agent of nocardiosis from yellowtails (*Seriola quinqueradiata*) and Japanese flounder (*Paralichlhys olivaceus*).

DNA G+C content (mol%): 66.8–67.4 (HPLC).

Type strain: ATCC 43993, CCUG 46828, CIP 104778, DSM 44129, NBRC 15557, JCM 3360, VKM Ac-1967.

Sequence accession no. (16S rRNA gene): AF 430039.

58. **Nocardia shimofusensis** Kageyama, Yazawa, Mukai, Kinoshita, Nishimura, Kroppenstedt and Mikami 2004f, 1930[VP]

shi.mo.fus.en′sis. N.L. fem. adj. *shimofusensis* of or pertaining to Shimofusa, a traditional geographical name for a Northern part of Chiba Prefecture in Japan, the source of the isolates.

Partially acid-fast actinomycete. Forms an extensive branched substrate mycelium that fragments into rod-shaped elements (0.5–0.7 × 0.9–1.7 µm). An orange to reddish orange substrate mycelium bears white to reddish white aerial hyphae. Does not produce diffusible pigments. Colonies 0.2–1.0 mm in diameter are produced on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Does not grow at 45°C. Susceptible (µg per disc) to imipenem (2.5), kanamycin (5), and tobramycin (2.5), and slightly susceptible to 5-fluorouracil (30) (Kageyama et al., 2004f). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, and smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, $C_{18:0}$, $C_{19:1}$ *cis*9, and $C_{20:1}$ *cis*11. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of representative *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between *Nocardia shimofuensis* strains and those of the type strains of related species are as follows: *Nocardia farcinica* (5–12%) and *Nocardia higoensis* (17–32%) (Kageyama et al., 2004f).

Source: soil samples collected in the city of Chonki and the village of Chyosei, Japan.

DNA G+C content (mol%): 68–69 (HPLC).

Type strain: DSM 44733, IFM 10311, JCM 12122, NBRC 100134, YZ 96.

Sequence accession no. (16S rRNA gene): AB108775.

59. **Nocardia sienata** corrig. Kageyama, Yazawa, Nishimura and Mikami 2004a, 1005[VP] (Effective publication: *Nocardia sienata* corrig Kageyama, Yazawa, Nishimura and Mikami 2004h, 275.)

si.e.na′ta. N.L. fem. adj. *sienata* sienna-colored, referring to the colony color of ochre-yellow of the strain.

Slightly acid–alcohol-fast actinomycete. Forms a pale yellow substrate mycelium that bears ochre-yellow aerial hyphae. At a late stage in the growth cycle, the hyphae fragment into rod-shaped elements. Does not form melanin pigments. Grows at 37°C but not at 45°C. Susceptible (µg per disc) to 5-fluorouracil (30), impenem (2.5), kanamycin (10), and tobramycin (2.5) (Kageyama et al., 2004h). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. The menaquinone profile is typical of the genus, as is the presence of mycolic acids in whole-organism methanolysates. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia carnea* (12%), *Nocardia flavorosea* (7–8%), and *Nocardia testacea* (51%) (Kageyama et al., 2004h).

Source (type strain): sputum of a patient with acute myeloid leukemia in Japan.

DNA G+C content (mol%): 68.3 (HPLC).

Type strain: DSM 44766, IFM 10088, JCM 12236, NBRC 100364.

Sequence accession no. (16S rRNA gene): AB121770.

Additional remarks: the original spelling, *Nocardia senatus* (*sic*) was corrected on validation according to Rule 61 of the Bacteriological Code (Lists Editor, 2004a).

60. **Nocardia soli** Maldonado, Hookey, Ward and Goodfellow 2001, 1619[VP] (Effective publication: Maldonado, Hookey, Ward and Goodfellow 2000, 375.)

so′li. L. gen. n. *soli* from the soil.

Acid–alcohol-fast actinomycete. Forms an extensively branched substrate mycelium that fragments into coccoid to rod-shaped elements. Brown to pale orange colonies with sparse aerial hyphae are formed on glucose-yeast extract agar. Colony elevation is convex to irregular, and colony margins are filamentous. Does not form diffusible pigments or grow at 45°C. 2-Deoxythymidine-5-*p*-nitrophenyl (*p*NP)-phosphate, *p*NP-phosphorylcholine, and *p*NP-β-D-xyloside are hydrolyzed. Sensitive (µg/ml) to cephaloridine (16), demethylchlortetracycline (16), gentamicin (8), rifampin (1), streptomycin (16), and tobramycin (1) (Maldonado et al., 2000). Sensitive to (µg per disc) imipenem (2.5), tobramycin (2.5) but not 5-fluorouracil (30) and kanamycin (30.0) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid.

Source: water collected from the River Thames at Medmenham, England.

DNA G+C content (mol%): not determined.

Type strain: CIP 107223, DSM 44488, JCM 11441, NBRC 100376, NCIMB 13760, W30.

Sequence accession no. (16S rRNA gene): AF430051.

61. **Nocardia speluncae** Seo, Yun and Lee 2007, 2934[VP]

spe.lun′ca.e. L. gen. n. *speluncae* of a cave, grotto or hole, referring to the site of isolation of the type strain.

Abundant aerial and substrate mycelia fragment into irregular rod-shaped elements. Yellow to orange substrate hyphae bear white to pinkish aerial hyphae. Grows well on yeast-extract-malt extract and oatmeal agars (ISP media 2 and 3) and on nutrient and tryptic soy agars. Grows at 10–37°C but not at 45°C; the pH for growth is 6.1–12.1. L-Valine is used as a simultaneous carbon and nitrogen source, but not L-phenylalanine. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and *cyclo*-$C_{19:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus.

Source (type strain): a soil sample collected from a natural cave on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 66.3±0.4 (HPLC).

Type strain: DSM 45078, JBRI 2006, JCM 14881, KCTC 19223, N2-11.

Sequence accession no. (16S rRNA gene): AM422449.

62. **Nocardia takedensis** Yamamura, Hayakawa, Nakagawa, Tamura, Kohno, Komatsu and Iimura 2005, 435[VP]

ta.ke.den′sis. N.L. fem. adj. *takedensis* of or pertaining to the Takeda Shrine, from where the organism was first isolated.

Branched substrate and aerial hyphae fragment into rod-like elements. An orange substrate mycelium bears a white aerial mycelium on which short aerial hyphae differentiate into chains of spores. Does not produce diffusible pigments. Grows well at 30°C, but does not grow at 45°C. Susceptible (µg per disc) to 5-fluorouracil (30), impenem (2.5), and tobramycin (2.5) but not kanamycin (30) (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of representative *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of *Nocardia beijingensis, Nocardia brasiliensis*, and *Nocardia tenerifensis* fall within the range 8.1–23.1% (Yamamura et al., 2005).

Source (type strain): a sediment sample collected from a moat surrounding the Takeda Shrine in Yamanashi Prefecture, Japan.

DNA G+C content (mol%): 68.6 (HPLC).

Type strain: DSM 44801, JCM 13313, MS1-3, NBRC 100417.

Sequence accession no. (16S rRNA gene): AB158277.

63. **Nocardia tenerifensis** Kämpfer, Buczolits, Jäckel, Grün-Wollny and Busse 2004, 383[VP]

te.ne.ri.fen′sis. N.L. fem. adj. *tenerifensis* of or belonging to Tenerife, from where the organism was isolated

An orange substrate mycelium fragments readily into irregular rod-shaped elements. Aerial hyphae are yellowish-white. Good growth occurs on nutrient agar and medium 65 at 25–30°C. L-Alanine-*p*-nitroanilide (*p*NA), 2-deoxythymidine 5′-*p*-nitrophenyl (*p*NP) phosphate, *p*NP-α-D- glucopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3-carboxyl *p*NA, *bis*-*p*NA phosphate, *p*NP-phenylphosphonate, *p*NP-phosphocholine, L-proline- *p*NA, and *p*NP-β-D-xylopyranoside are hydrolyzed, but not *p*NP-β-D-glucuronide or *o*-nitrophenyl-β-D-galactopyranoside. Susceptible (µg per disc) to impenem (2.5) and tobramycin (2.5) but not to 5-fluorouracil (30) and kanamycin (30) (Hoshino et al., 2007). Additional phenotypic properties are cited in Table 39. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and 10-methyl-$C_{16:0}$, smaller proportions (<10%) of $C_{18:0}$, and traces of $C_{10:0}$, $C_{14:0}$, $C_{17:0}$, $C_{16:1}$ *cis*9, $C_{17:1}$ *cis*5, $C_{18:1}$ *cis*6, and $C_{20:2}$ *cis*9. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those from reference *Nocardia* strains. Menaquinone and polar lipid profiles are typical of the genus, apart from the presence of significant amounts of phosphatidylglycerol. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia beijingensis* (25.4%), *Nocardia brasiliensis* (29.3%), *Nocardia farcinica* (15.8%), and *Nocardia transvalensis* (16.2%) (Kämpfer et al., 2004).

Source (type strain): soil collected in Tenerife, Spain.

DNA G+C content (mol%): not determined.

Type strain: CCUG 49019, CIP 107929, DSM 44704, GW39-1573, JCM 12693, NBRC 101015.

Sequence accession no. (16S rRNA gene): AJ556157.

64. **Nocardia terpenica** Hoshino, Watanabe, Iida, Suzuki, Kudo, Kogure, Yazawa, Ishikawa, Kroppenstedt and Mikami 2007, 1459[VP]

ter.pe′ni.ca. N.L. n. *terpenum* terpene; L. suff. *-icus -a -um* suffix used with various meanings; N.L. fem. adj. *terpenica* referring to the ability to produce terpenoid antibiotics.

Acid–alcohol-fast actinomycete. Forms a colorless to beige substrate mycelium that fragments into irregular, long rod-shaped elements (0.2–0.5 × 0.6–1.4 µm) towards the end of the growth cycle. If present, aerial hyphae are scanty on most media. Colonies 1.0–3.5 mm in diameter formed on Mueller–Hinton II agar supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Susceptible (µg per disc) to tobramycin (2.5) but not to 5-fluorouracil (30), impenem (10), and kanamycin (30) (Hoshino et al., 2007). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{18:1}$ *cis*9, $C_{16:1}$ *cis*11, $C_{17:1}$ *cis*9, $C_{17:0}$, and $C_{18:0}$, and traces of $C_{12:0}$, $C_{14:0}$, $C_{15:1}$ *cis*10, $C_{16:1}$ *cis*7, and 10-methyl-$C_{16:0}$. Mycolic acids have between 52–60 carbon atoms with C56 as the major component. The menaquinone profile is typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia nova*, a closely related species, is 48% (Hoshino et al., 2007).

Source (type strain): sputum of a patient with lung nocardiosis at Okayama, Japan.

DNA G+C content (mol%): 65.4 (HPLC).

Type strain: DSM 44935, IFM 0706, JCM 13033, NBRC 100888.

Sequence accession no. (16S rRNA gene): AB201298.

65. **Nocardia testacea** corrig. Kageyama, Yazawa, Nishimura and Mikami 2004a, 1005[VP] (Effective publication: corrig. Kageyama, Yazawa, Nishimura and Mikami 2004h, 274.)

tes.ta′ce.a. L. fem. adj. *testacea* brick-colored, referring to the brick colony color.

Acid–alcohol-fast actinomycete. Forms a substrate mycelium that fragments into irregular, rod-shaped elements. A dark orange to brick colored substrate mycelium bears a whitish aerial mycelium which has a reddish tinge. Does not produce melanin pigments. Grows between 27 and 45°C. Does not use L-phenylalanine or L-valine as sole carbon and nitrogen sources. Susceptible (μg per disc) to impenem (2.5), kanamycin (5.0), tobramycin (2.5) but not to 5-fluorouracil (30) (Kageyama et al., 2004h). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. The menaquinones are typical of the genus, as is the presence of mycolic acids in whole-organism methanolysates. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Nocardia carnea* (8.3%), *Nocardia flavorosea* (6.6%), and *Nocardia sienata* (51%) (Kageyama et al., 2004h).

Source (type strain): sputum of a patient with a nontuberculous mycobacterial infection in Japan.

DNA G+C content (mol%): 68.6 (HPLC).

Type strain: DSM 44765, IFM 0937, JCM 12235, NBRC 100365.

Sequence accession no. (16S rRNA gene): AB192415.

Additional remarks: the original spelling, *Nocardia testaceus* (*sic*) was corrected on validation according to Rule 61 of the Bacteriological Code (Lists Editor, 2004a). In addition, the specific epithet is a L. adj. not a N.L. gen. n. as cited in the paper by Kageyama et al. (2004h).

66. **Nocardia thailandica** Kageyama, Poonwan, Yazawa, Suzuki, Kroppenstedt and Mikami 2005b, 547[VP] (Effective publication: *Nocardia thailandica* Kageyama, Poonwan, Yazawa, Suzuki, Kroppenstedt and Mikami 2004c, 32.)

thai.lan′di.ca. N.L. fem. adj. *thailandica* of or pertaining to Thailand, the source of the strain.

Branched substrate hyphae fragment into bacteroid, rod-shaped elements (0.4–0.6 × 0.8–1.6 μm). Visible aerial hyphae occur on most standard media, including brain heart infusion agar. Colonies 0.2–1.2 mm in diameter are produced on Mueller–Hinton II agar supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Grows at 37°C, but not at 45°C. Susceptible (μg per disc) to impenem (2.5), 5-fluorouracil (30), kanamycin (5.0), and tobramycin (2.5) (Hoshino et al., 2007).

Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$, smaller proportions (<10%) of $C_{15:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, 10-methyl-$C_{17:0}$, $C_{18:1}$ *cis*9, and $C_{19:1}$ *cis*9, and traces of $C_{14:0}$, $C_{15:1}$ *cis*9, 10-methyl-$C_{16:0}$, $C_{19:0}$, and $C_{20:0}$. Mycolic acids co-migrate on thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. The DNA–DNA relatedness value between the type strain and the corresponding strain of *Nocardia asteroides*, a closely related species, is below 12% (Kageyama et al., 2004c).

Source: pus of a Thai patient.

DNA G+C content (mol%): 72 (HPLC).

Type strain: DSM 44808, IFM 10145, JCM 12356, NBRC 100428.

Sequence accession no. (16S rRNA gene): AB126874.

67. **Nocardia transvalensis** Pijper and Pullinger 1927, 338[AL] ["*Actinomyces transvalensis*" Pijper and Pullinger 1927, "*Proactinomyces transvalensis*" (Pijper and Pullinger 1927) Krasil'nikov 1941.]

trans.val.en′sis. N.L. fem. adj. *transvalensis* of or pertaining to the Transvaal, South Africa.

Partially acid-fast actinomycete. Produces pale tannish cream or purplish colonies which bear moderate to abundant aerial hyphae. Does not form soluble pigments. Grows at 30–37°C but not at 45°C. L-Alanine-*p*-nitroanilide (*p*NA), 2-deoxythymidine 5′ *p*-nitrophenyl (*p*NP) phosphate, *p*NP-α-D-glucopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3-carbonyl-*p*NA, *o*-nitrophenyl-β-D-galactopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, L-proline *p*NA, and *p*NP-β-D-xylopyranoside are hydrolyzed but not *p*NP-β-D-glucuronide. Proline and serine are used as simultaneous carbon and nitrogen sources, but not acetamide, L-alanine, or gelatin. Susceptible (μg per disc) to imipenem (2.5) but not to 5-fluorouracil (30), kanamycin (30.0), and tobramycin (10.0) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$ and $C_{18:0}$, and traces of $C_{10:0}$, $C_{12:0}$, $C_{15:0}$, $C_{17:0}$, $C_{16:1}$ *cis*9, $C_{17:1}$ *cis*8, $C_{18:1}$ *cis*7, $C_{15:0}$ *cis* 3-OH, and $C_{17:0}$10-methyl. DNA–DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: (i) *Nocardia abscessus* (6%), *Nocardia asteroides* (11%), *Nocardia nova* (6%), *Nocardia paucivorans* (6%), *Nocardia pseudobrasiliensis* (12%), *Nocardia vaccinii* (9%), and *Nocardia vinacea* (5%) (Kinoshita et al., 2001) and (ii) *Nocardia tenerifensis* (23.6%) (Kämpfer et al., 2004).

Source (type strain): mycetoma of the foot in South Africa.

DNA G+C content (mol%): 67.0 (T_m).

Type strain: ATCC 6865, CCUG 45937, CIP 104841, DSM 43405, NBRC 15921, IMET 7500, JCM 9099, NRRL B-16037, VKM Ac-867.

Sequence accession no. (16S rRNA gene): AF430047.

68. **Nocardia uniformis** (*ex* Marton and Szabó 1959) Isik, Chun, Hah and Goodfellow 1999a, 1229[VP] ("*Nocardia uniformis*" Marton and Szabó 1959)

u.ni.for′mis. L. fem. adj. *uniformis* having only one form, uniform.

Acid–alcohol-fast actinomycete. Forms an extensive branched substrate mycelium that fragments *in situ* into coccoid to rod-shaped elements (0.7–1.1 × 1.1–1.4 µm). A yellowish orange substrate mycelium bears whitish, sparse to abundant, aerial hyphae. Colony elevation is convex to irregular and colony margins are filamentous. Grows at 14–40°C but not at 10°C, and at pH 6.0–10.0 but not at pH 5.0. L-Alanine-*p*-nitroanilide (*p*NA), 2-deoxythymidine 5′-*p*-nitrophenyl (*p*NP) phosphate, *p*NP-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *p*NP-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-β-D-xylopyranoside are hydrolyzed but not *p*NP-β-D-glucuronide, L-glutamate-γ-3-carbonyl-*p*NA, *p*NP-phosphorylcholine, or L-proline. Susceptible (µg per disc) to 5-fluorouracil (30) and tobramycin (2.5) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{15:0}$, 10-methyl-$C_{16:0}$, $C_{17:1}$ *cis*9, $C_{17:0}$, 10-methyl-$C_{17:0}$, $C_{19:1}$ *cis*9, and traces of $C_{14:0}$, and $C_{15:1}$ *cis*10. The menaquinone profile is characteristic of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia inohanensis* (22%), *Nocardia niigatensis* (25%), *Nocardia otitidiscaviarum* (33%), *Nocardia seriolae* (33%), and *Nocardia yamanashiensis* (27%) (Kageyama et al., 2004i).

Source: a degraded solonchak solonets soil collected from the Hortobagy steppe in eastern Hungary.

DNA G+C content (mol%): not determined.

Type strain: CBS 224.60, CIP 104824, DSM 43136, IFO (now NRBC) 13702, JCM 3224, NCIB 963.

Sequence accession no. (16S rRNA gene): AF430044.

69. **Nocardia vaccinii** Demaree and Smith 1952, 338[VP]

vac.ci′ni.i. N.L. gen. n. *vaccinii* of *Vaccinium*, the generic name of blueberry; referring to the plant from which the type strain was isolated.

Partially acid-fast actinomycete. Forms cream to peach colonies which bear moderate to sparse white aerial hyphae. Aerial hyphae rarely differentiate into spores. Grows best at 25–28°C but poorly at 37°C. Does not hydrolyze 2-deoxythymidine-5′-*p*-nitrophenyl (*p*NP)-phosphate, *p*NP- phosphorylcholine, or *p*NP-β-D-xyloside. Does not use acetamide, L-alanine, gelatin, proline, or serine as simultaneous carbon and nitrogen sources. Susceptible (µg per disc) to 5-fluorouracil (30), imipenem (2.5), kanamycin (5.0), and tobramycin (2.5) (Kageyama et al., 2005d). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{16:1}$ *cis*9 and $C_{17:1}$ *cis*10, and traces of $C_{14:0}$, $C_{15:0}$, $C_{16:1}$ *cis*7, $C_{17:0}$, $C_{18:0}$, $C_{19:1}$, and $C_{19:0}$. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: (i) *Nocardia abscessus* (5%), *Nocardia asteroides* (8%), *Nocardia nova* (8%), *Nocardia paucivorans* (5%), *Nocardia pseudobrasiliensis* (8%), *Nocardia transvalensis* (11%), and *Nocardia vinacea* (4%) (Kinoshita et al., 2001), and (ii) *Nocardia africana* (10%), *Nocardia cerradoensis* (43%), *Nocardia nova* (10%), *Nocardia veterana* (42%), *Nocardia vinacea* (5%), and *Nocardia vermiculata* (6%) (Kageyama et al., 2004c).

Source (type strain): bud-proliferating galls on blueberry (*Vaccinium* spp.).

DNA G+C content (mol%): not determined.

Type strain: ATCC 11092, CIP 104899, DSM 43285, ICMP 15782, IMET 7503, JCM 3395, NBRC 15922, NCPPB 954, NRRL WC-3500, VKM Ac-856.

Sequence accession no. (16S rRNA gene): AF430045.

Additional remarks: the strain ICMP 5814, previously cited as the type strain of *Nocardia vaccinii*, is a *Staphylococcus* sp. Consequently, the strain ICMP 5814 has been replaced by strain ICMP 15782 (List of Prokaryotic Names with Standing in Nomenclature, http://www.bacterio.cict.fr).

70. **Nocardia vermiculata** Kageyama, Poonwan, Yazawa, Suzuki, Kroppenstedt and Mikami 2005b, 547[VP] (Effective publication: *Nocardia vermiculata* Kageyama, Poonwan, Yazawa, Suzuki, Kroppenstedt and Mikami 2004c, 30.)

ver.mi.cu.la′ta. L. fem. part. adj. *vermiculata* in the form of worms, referring to the morphology of the aerial mycelium.

Partially acid-fast actinomycete. Produces branched substrate hyphae that fragment into oval to rod-shaped elements (0.4–0.7 × 0.7–1.0 µm). A beige substrate mycelium bears a moderate orange to pale orange brown aerial mycelium. The aerial mycelium shows primitive spiral-like structures (worm-like structures). Colonies 0.3–1.0 µm in diameter are formed on Mueller–Hinton II agar supplemented with glucose (0.2%, w/v). Aerial hyphae differentiate into short chains of spores. A faint diffusible pigment is formed. Grows at 37°C but not at 45°C. Susceptible (µg per disc) to 5-fluorouracil (30), imipenem (2.5), kanamycin (5), and tobramycin (2.5) (Hoshino et al., 2007). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$, smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{16:1}$ *cis*8, $C_{16:1}$ *cis*9, $C_{17:1}$ *cis*9, $C_{17:0}$, and $C_{18:0}$ 10-methyl, and traces of $C_{12:0}$, $C_{13:1}$, $C_{17:1}$ *cis*10, 10-methyl-$C_{17:0}$, $C_{18:1}$ *cis*11, and $C_{19:1}$ *cis*9. Mycolic acids co-migrate on one dimensional thin-layer chromatography with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia africana* (10%), *Nocardia cerradoensis* (9%), *Nocardia nova* (11%), *Nocardia vaccinii* (10%), *Nocardia veterana* (1%), and *Nocardia vinacea* (2%) (Kageyama et al., 2004c).

Source: sputum of a Japanese patient in 1985.

DNA G+C content (mol%): 67 (HPLC).

Type strain: DSM 44807, IFM 0391, JCM 12354, NBRC 100427.

Sequence accession no. (16S rRNA gene): AB126873.

71. **Nocardia veterana** Gürtler, Smith, Mayall, Pötter-Reinemann, Stackebrandt and Kroppenstedt 2001, 935[VP] (Effective publication: Gürtler, Smith, Mayall, Põtter-Reinemann, Stackebrandt and Kroppenstedt 2001, 935.)

ve.te.ra′na. L. fem. adj. *veterana* old in service (as soldiers), referring to the veteran's hospital where the organism was isolated.

A beige substrate mycelium bears scant, dirty white, aerial hyphae. The highly branched substrate and aerial mycelium do not fragment. The reverse side of colonies is yellowish. Grows at 25 and 45°C. *p*-Nitrophenyl (*p*NP) phosphorylcholine is hydrolyzed, but not 2-deoxythymidine-5-*p*NP phosphate, or *p*NP-β-D-xyloside. Does not use acetamide, L-alanine, gelatin, proline, or serine as simultaneous carbon and nitrogen sources. Susceptible (μg per disc) to 5-fluorouracil (30) and imipenem (2.5); moderately susceptible to kanamycin (10); resistant to tobramycin (10) (Kageyama et al., 2005d). Additional phenotypic properties are shown in Table 39. Whole-cell hydrolysates contain arabinose as the characteristic sugar, and *meso*-diaminopimelic acid as the only diamino acid. Muramic acid moieties are *N*-glycolated. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{17:0}$, $C_{18:0}$, and traces of $C_{16:1}$ *cis*7, $C_{17:1}$, and $C_{19:1}$. Mycolic acids have 54–64 carbon atoms with C56, C58, and C60 as major components. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: (1) *Nocardia vaccinii* (31%), (Gurtler et al., 2001), and (ii) *Nocardia africana* (7%), *Nocardia cerradoensis* (3.8%), *Nocardia nova* (7%), *Nocardia vaccinii* (46%), *Nocardia vermiculata* (7%), and *Nocardia vinacea* (3%), (Kageyama et al., 2004c). A causative agent of pulmonary disease in immunocompromised patients.

Source (type strain): a bronchial lavage specimen of a patient with a past history of tubercular pleurisy who presented with bilateral upper lobe lesions in a hospital at Heidelberg, Australia.

DNA G+C content (mol%): not determined.

Type strain: CCUG 46118, CIP 107095, DSM 44445, JCM 11307, M157222, NBRC 100344, NRRL B-24136.

Sequence accession no. (16S rRNA gene): AF430055.

72. **Nocardia vinacea** Kinoshita, Homma, Igarashi, Ikeno, Hori and Hamada 2002, 3[VP] (Effective publication: Kinoshita, Homma, Igarashi, Ikeno, Hori and Hameda 2001, 4.)

vi.na′ce.a. L. fem. adj. *vinacea* of or belonging to wine or to the grape, referring to the pale reddish purple diffusible pigment.

Colorless pale yellow to pale brown substrate mycelium undergoes fragmentation. Straight, flexuous to spiral aerial hyphae differentiate into cylindrical and ellipsoidal spore-like elements (0.4–0.6 × 0.8–1.8 μm). Pale reddish purple soluble pigments may be produced. Does not form melanin pigments. Grows at 20–37°C but not at 45°C. Susceptible (μg per disc) to imipenem (10), tobramycin (2.5) but not to 5-fluorouracil and kanamycin (30) (Kageyama et al., 2005d). Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$ 10-methyl, and $C_{16:1}$ *cis*9. Mycolic acids have 48–56 carbon atoms. Menaquinone and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species, namely *Nocardia abscessus, Nocardia africana, Nocardia asteroides, Nocardia cerradoensis, Nocardia nova, Nocardia paucivorans, Nocardia pseudobrasiliensis, Nocardia transvalensis, Nocardia vaccinii, Nocardia veterana*, and *Nocardia vermiculata* range from 5 to 13% (Kageyama et al., 2001, 2004c).

Source (type strain): a soil sample collected at Suwa-shi, Nagano, Japan.

DNA G+C content (mol%): 65 (HPLC).

Type strain: DSM 44638, NBRC 16497, JCM 10988, MK703-102F1.

Sequence accession no. (16S rRNA gene): AB024312.

Additional remarks: according to Rules 27(3) and 30 of the Bacteriological Code, this name is not validly published inasmuch as the effective publication only documents the deposit of the type strain in a single recognized culture collection (Euzéby and Tindall, 2004). However, according to Judicial Opinion 81, *Nocardia vinacea* Kinoshita et al. 2002 should be considered to be validly published (Judicial Commission of the International Committee on the Systematics of Prokaryotes, 2008).

73. **Nocardia wallacei** Conville, Brown, Steigerwalt, Brown-Elliott and Witebsky 2009, 1183[VP] (effective publication)

wal.la′ce.i. N.L. masc. gen. n. *wallacei* of Wallace, named in honor of Richard J. Wallace, Jr, in recognition of his contribution to the understanding of the taxonomy and drug susceptibility of *Nocardia* species.

Acid-fast positive actinomycete. Form a branched substrate mycelium that bears aerial hyphae. Grows at 25–45°C and optimally at 35°C. Does not use acetamide as a simultaneous carbon and nitrogen source. The type strain is susceptible to ceftriaxone, ciprofloxacin, and linezolid but not to amikacin and clarithromycin (Conville et al., 2008). Grows in the presence of lysozyme. Does not use acetamide as a simultaneous carbon and nitrogen source. Additional phenotypic properties are cited in Table 39. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia blacklockiae* (53+ 8.5%) and *Nocardia transvalensis* (44±10.5%) (Conville et al., 2008).

Source (type strain): pleural fluid and sputum of a patient with underlying health problems.

DNA G+C content (mol%): 65 (T_m).

Type strain: ATCC 49873, DSM 45136.

Sequence accession no. (16S rRNA gene): EU099357.

Additional remarks: the taxonomic integrity of *Nocardia wallacei* is supported by results from 65-kDa heat-shock protein and s*ecA1* gene sequence analyses (Conville et al., 2008).

74. **Nocardia xishanensis** Zhang, Liu and Goodfellow 2004, 2304[VP]

xi.shan.en′sis. N.L. fem. adj. *xishanensis* of or belonging to Xishan Mountain, the source of the soil from which the type strain was isolated.

Slightly acid–alcohol-fast actinomycete which forms an extensive branched substrate mycelium that fragments into coccoid and rod-shaped elements. A yellow to orange substrate mycelium bears sparse to abundant, white aerial hyphae on modified Sauton's agar. Does not form diffusible pigments. Colony elevation is convex to irregular and colony margins filamentous. Grows at 22–38°C but not at 45°C, and from pH 5.5 to 10. L-Alanine, L-proline, and L-valine are used as simultaneous carbon and nitrogen sources, but not acetamide, L-asparagine, L-aspartate, gelatin, D-glucosamine, L-leucine, L-phenylalanine, or L-serine. Sensitive (µg per disc) to chloramphenicol (30), erythromycin (15), midecamycin (15), minocycline (50), rifampin (5), streptomycin (10), tobramycin (10), and vancomycin (30) but not to gentamicin (10) (Zhang et al., 2004). Sensitive (µg/ml) to arbekacin (4), ampicillin (4), clarithromycin (<0.006), cefotiam (2), and erythromycin (<0.006) (Iida et al., 2006). Resistant to lysozyme. Grows in the presence of NaCl at 3%, w/v, but not at 5%, w/v. Additional phenotypic properties are cited in Table 39. Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$, $C_{18:1}$ *cis*9, and $C_{18:0}$ 10-methyl, and a smaller proportion (<10%) of $C_{18:0}$. Mycolic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile and polar lipid profiles are typical of the genus. DNA–DNA relatedness values between the type strain and the corresponding strains of related species are as follows: *Nocardia abscessus* (39%) and *Nocardia asteroides* (35%) (Zhang et al., 2004).

Source (type strain): a soil sample collected from Xishan mountain, Beijing, China.

DNA G+C content (mol%): 68.8 (T_m).

Type strain: 276 AS 4.1860, CGMCC 4.1860, DSM 44895, JCM 12160.

Sequence accession no. (16S rRNA gene): AY333115.

75. **Nocardia yamanashiensis** Kageyama, Yazawa, Nishimura and Mikami 2004i, 568[VP]

ya.ma.na.shi.en′sis. N.L. fem. adj. *yamanashiensis* of or pertaining to Yamanashi prefecture of Japan, the source of the type strain.

Partially acid–alcohol-fast actinomycete. Forms a grayish-tan to tan branched substrate mycelium that fragments into bacteroid, coccoid, and rod-shaped elements. Aerial hyphae are sparse on most media and are only visible microscopically. Colonies 1.0–1.9 mm in diameter are formed on Mueller–Hinton II medium supplemented with glucose (0.2%, w/v) after 7 d at 30°C. Susceptible (µg per disc) to impenem (2.5), kanamycin (2.5), and tobramycin (2.5) and slightly susceptible to 5-fluorouracil (30) (Kageyama et al., 2004c). Whole-cell hydrolysates contain arabinose and galactose as characteristic sugars, and *meso*-diaminopimelic acid as the principal diamino acid. Muramic acids co-migrate on one-dimensional thin-layer chromatography of whole-organism methanolysates with those of reference *Nocardia* strains. The menaquinone profile is typical of the genus. DNA–DNA relatedness values between the type strain and corresponding strains of related species are as follows: *Nocardia inohanensis* (40%), *Nocardia niigatensis* (21%), *Nocardia otitidiscaviarum* (13%), *Nocardia seriolae* (20%), and *Nocardia uniformis* (8.2%) (Kageyama et al., 2004i).

Source (type strain): clinical material.

DNA G+C content (mol%): 69.2 (HPLC).

Type strain: DSM 44669, IFM 0265, JCM 11893, NBRC 100130.

Sequence accession no. (16S rRNA gene): AB092561.

Genus II. **Gordonia** (Tsukamura 1971) Stackebrandt, Smida and Collins 1988, 345[VP]

Michael Goodfellow, Yashawant Kumar and Luis A. Maldonado

Gor.do′ni.a. N.L. fem. n. *Gordonia* named after Ruth E. Gordon, a celebrated bacterial systematist.

Aerobic, Gram-stain-positive to Gram-stain-variable, nonspore-forming actinomycetes that are **usually partially acid–alcohol-fast**. **Nonmotile, short rods and cocci** (0.5–1.0 × 1.0–2.5 µm) **occur singly, in pairs, in V-shaped arrangements, or as short chains**. **Elementary branched hyphae which fragment into rod- and coccoid-like elements are formed by some species.** Colonial appearance ranges from convex, shiny and smooth to rough, matt and folded with irregular margins. Colonies may be cream, beige, light yellow, or tan through to apricot, orange, pink, or red. Chemo-organotrophic with an oxidative type of metabolism. Mycobactins are formed. Catalase-positive, arylsulfatase-negative, and sensitive to lysozyme. Most strains grow well between 20 and 37°C.

Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid, arabinose and galactose. The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-glycolated. **Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids, major proportions of straight chain saturated, unsaturated and 10-methyloctadecanoic (tuberculostearic) fatty acids, and dihydrogenated menaquinones with nine isoprene units as the predominant isoprenologue. Mycolic acids have 46–70 carbon atoms and 1–6 double bonds. The fatty acid esters released on pyrolysis gas chromatography of mycolic acid esters have 16–18 carbon atoms.** The phylogenetic position of *Gordonia*, as determined by 16S rRNA gene sequence analysis, is in the family *Nocardiaceae*.

Gordoniae are widely distributed in aquatic and terrestrial habitats, notably in soils, marine sediments, and wastewater systems. Members of some species are opportunistic pathogens for man and animals.

DNA G+C content (mol%): 63–69 (HPLC, T_m).

Type species: **Gordonia bronchialis** (Tsukamura 1971) Stackebrandt, Smida and Collins 1988, 345[VP].

Further descriptive information

Phylogeny. *Gordonia* is the type genus of the family *Gordoniaceae* Stackebrandt et al. (1997) which also includes the genera *Millisia* Soddell et al. 2006a, *Skermania* Chun et al., (1997), and *Williamsia* Kämpfer et al. (1999). These taxa were proposed to form a branch in the *Corynebacteriales* 16S rRNA gene tree and distinct phyletic lines in the *Gordoniaceae* 16S rRNA gene tree (Figure 93a). However, further analyses with more comprehensive collections of outgroups suggest that these genera should be combined within the family *Nocardiaceae* (Zhi et al., 2009; Ludwig et al. – the roadmap to this volume). While the family *Gordoniaceae* is not used in the current work, the classification of *Gordonia* is far from certain based upon the current evidence.

In contrast to the 16S rRNA gene, greater resolution is found between members of the genus *Gordonia* in phylogenetic trees based on GyrB amino acid sequences (Figure 93b; Shen et al., 2006). Shen and his co-workers have also shown that gordoniae have much lower interspecies *gyrB* substitution rates than members of the genera *Corynebacterium*, *Nocardia*, and *Rhodococcus*.

Chemotaxonomic and 16S rRNA gene sequence data have been instrumental in clarifying the taxonomic positions of misclassified mycolic acid-containing taxa (Blackall et al., 1994; Goodfellow et al., 1982b), as exemplified by the transfer of *Nocardia amarae* and *Rhodococcus aichiensis* to the genus *Gordonia* as *Gordonia amarae* and *Gordonia aichiensis* (Klatte et al., 1994b). These species also fall within the evolutionary radiation occupied by the genus *Gordonia* in the *gyrB* tree (Figure 93b).

Cell morphology. Most gordoniae form short rods and cocci. Cells in early growth phase are rods and those in exponential phase are cocci; such strains exhibit a typical rod–coccus life cycle. Some species, including *Gordonia lacunae*, *Gordonia polyisoprenivorans, Gordonia shandongensis*, and *Gordonia soli*, produce elementary branching hyphae which fragment into rod- and coccoid-like elements (Le Roes et al., 2008; Linos et al., 1999; Shen et al., 2006a). *Gordonia defluvii* shows acute-angled and right-angled branching (Soddell et al., 2006a), a cellular morphology that is intermediate between the right-angled branching pattern typical of *Gordonia amarae* (Klatte et al., 1994b; Lechevalier and Lechevalier, 1974) and the "pine-tree-like" morphology of *Skermania piniformis* (Blackall et al., 1989; Chun et al., 1997). *Gordonia amarae* strains form moderately branched, non-fragmenting, vegetative hyphae in undisturbed culture; the hyphae usually show branching both in the natural environment (foam on the surface of aeration tanks in activated-sludge sewage treatment plants) and *in situ* under phase-contrast microscopy (Lechevalier and Lechevalier, 1974). These workers also noted that many newly isolated strains showed banded hyphae, a characteristic which was lost on prolonged cultivation. Sections through banded hyphae showed numerous cross walls, laminated walls, irregularly thickened cells and many mesosomes.

Cell envelope composition. Gordoniae have (a) a peptidoglycan composed of *N*-acetylglucosamine, D-alanine, L-alanine, and D-glutamic acid with *meso*-diaminopimelic acid (*meso*-A_2pm) as the diamino acid, and muramic acid in the *N*-glycolated form; (b) arabinose and galactose as diagnostic wall sugars (i.e. whole-organism sugar pattern type A *sensu* Lechevalier and Lechevalier (1970); (c) a phospholipid pattern consisting of diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides (i.e. phospholipid pattern type II *sensu* Lechevalier et al., 1977, 1981b); (d) a fatty acid profile consisting of major amounts of straight-chain, unsaturated and tuberculostearic fatty acids (i.e. a type IV fatty acid pattern *sensu* Lechevalier et al., 1977); (e) mycolic acids with 46–70 carbon atoms (Alshamaony et al., 1976b), and (f) dihydrogenated menaquinones with nine isoprene units as the predominant isoprenologue (Collins et al., 1985). Gordoniae have fatty acid profiles rich in oleic, palmitic, palmitoleic, and tuberculostearic acids though quantitative and qualitative species-specific and intraspecific differences have been reported (Kim et al., 2003; Klatte et al., 1994b; Shen et al., 2006a). A lipoglycan structurally related to mycobacterial lipoarabinomannan has been detected in *Gordonia rubripertincta* (*sic*) (Flaherty and Sutcliffe, 1999).

Selective ion monitoring gas chromatography-mass spectrometry (SIM GC-MS) analysis provided a more detailed profile than GC-MS of the mycolic acid composition of a *Gordonia amarae* strain isolated from activated sludge foam (Stratton et al., 1999). This organism was shown to contain many shorter chain lengths and more fully saturated mycolic acids than corresponding data from previous studies on *Gordonia* strains. Stratton and her colleagues suggested that gordoniae isolated from activated sludge foams might have a different mycolic acid composition than *Gordonia* type strains.

Colony morphology. Gordoniae grow well on standard agar media used to cultivate actinomycetes. Smooth to slightly wrinkled, flat to raised or umbonate colonies with irregular margins are formed on glucose-yeast extract agar (Gordon and Mihm, 1962a). Colonies range from 2 to 10 mm in diameter, and may be opaque, beige to peach, cream, pale gray, orange, red, white, yellow, or deep pink in color. *Gordonia amarae* and *Gordonia defluvii* form microscopically visible aerial hyphae. Diffusible pigments are not produced. Strains growing on glucose-yeast extract isolation plates may show pale yellow or orange central papilla which are lost on transfer to fresh plates. Some strains, such as the type strains of *Gordonia alkanivorans* and *Gordonia westfalica*, form smooth and rough colonies (Kummer et al., 1999; Linos et al., 2002); cultures showing smooth colonies can generate rough colonies, a change which seems to be irreversible. There is evidence that glycosylated peptidolipids influence the colony morphology of *Gordonia hydrophobica* (Moorman et al., 1997).

Nutritional and growth conditions. *Gordonia* strains grow well on standard nutrient media, such as modified Bennett's (Jones, 1949), modified Sauton's (Mordarska et al., 1972), and glucose-yeast extract (Gordon and Mihm, 1962a) agars. In general, they grow well between 20°C and 37°C, but not at 5°C or 45°C. The pH growth range is 5–10.

Metabolism. Gordoniae are aerobic, catalase-positive, chemo-organotrophic actinomycetes which have an oxidative metabolism. They degrade a broad range of organic substrates, and use a wide range of sole carbon sources, and sole carbon and nitrogen compounds (Goodfellow et al., 1982b, 1982c, 1996; Kotani et al., 2003; Santos et al., 2006). They also cleave diverse 7-amino-4-methylcoumarin (7AMC) and 4-methylumbelliferone (4MU-) conjugated fluorogenic substrates (Goodfellow et al., 1991a).

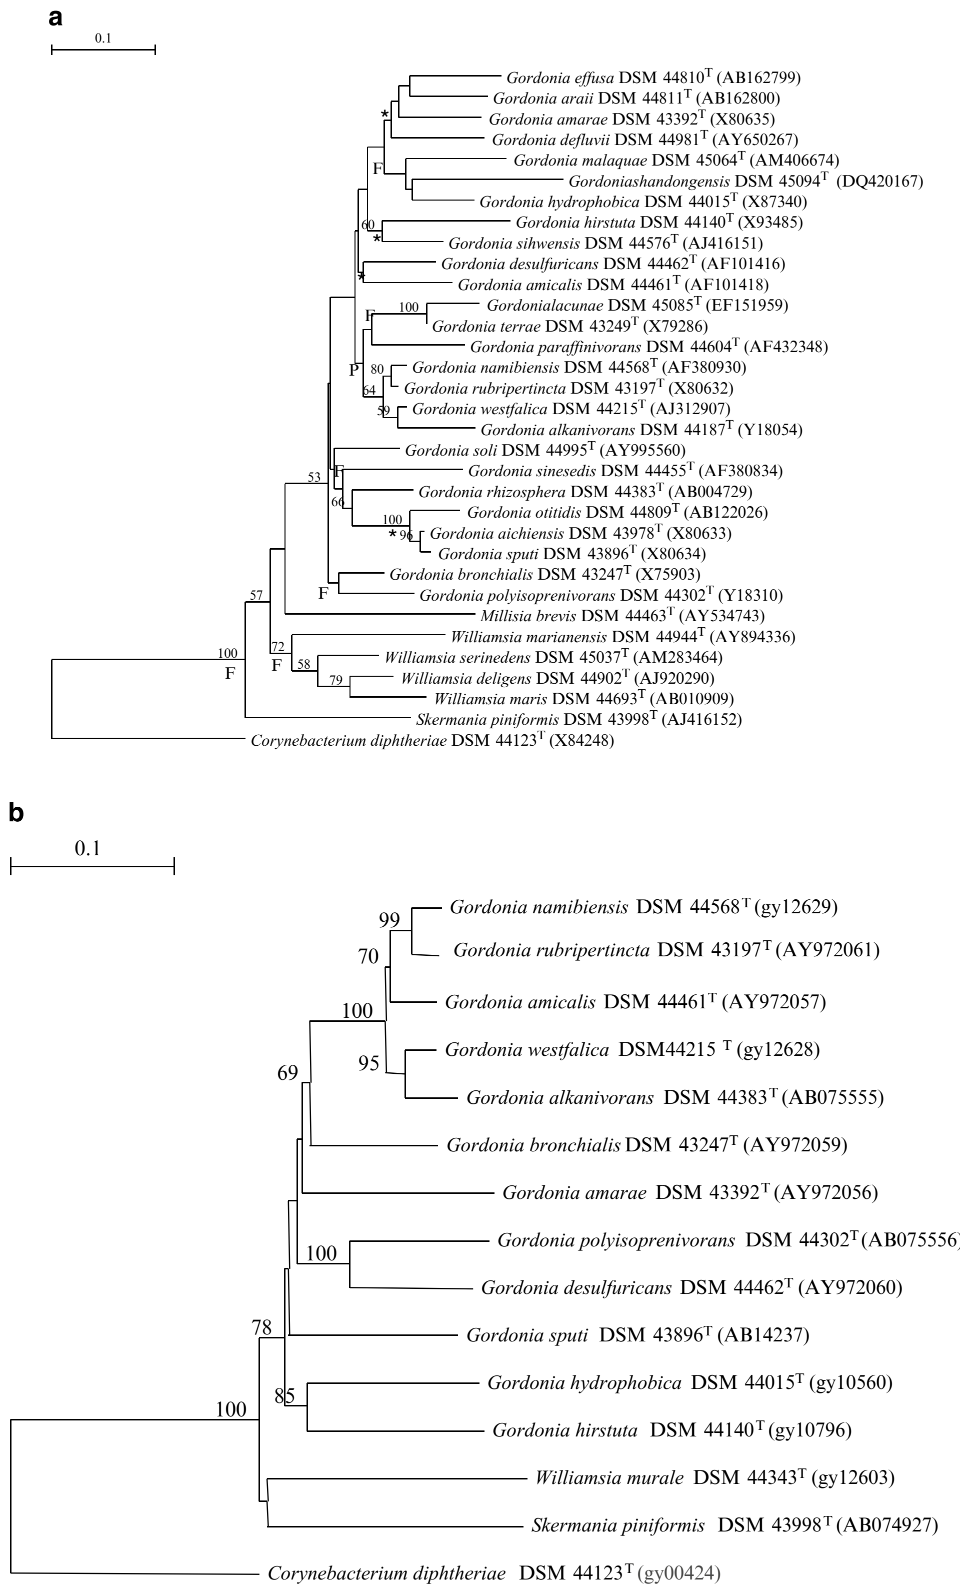

FIGURE 93. (a) Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing relationships between type strains of species in *Gordonia, Millisia, Skermania* and *Williamsia*; *Corynebacterium diphtheriae* was the out-group. Asterisks indicate branches of the tree that were found using the least-squares and maximum-parsimony tree-making algorithms. F indicates branches that were recovered using the least-squares method. The numbers at the nodes indicate the levels of bootstrap support derived from a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. Bar = 0.1 substitutions per nucleotide position. (b) Neighbour-joining tree based on *gyrB* amino acid sequences showing relationships between genera classified in the family *Gordoniaceae* and some representative members of other genera belonging to the order *Corynebacteriales.*

Gordoniae encompass a rich reservoir of metabolic diversity which makes them attractive candidates for the bioremediation of toxic wastes, as biocatalysts, and for commercially useful industrial processes (Arenskötter et al., 2004). The presence of the dibenzothiophene-desulfurization pathway in *Gordonia amicalis* DSM 44461^{T} is consistent with their emerging status as a source of metabolic diversity rivalling that of rhodococci (Kim et al., 2000). Other gordoniae that have desulfurization pathways include *Gordonia aichiensis* strain 51 (Finkel'shtein et al., 1999), *Gordonia rubropertincta* (*sic*) strain TO8 (Matsui et al., 2001), *Gordonia* strain F.5.25.8 (Santos et al., 2006), and *Gordonia* strain GYSK1 (Rhee et al., 1998), all of which remove sulfur from dibenzothiophene, and *Gordonia desulfuricans* NCIB 40817 and NCIB 40616^{T} which have a unique sulfur-scavenging pathway whereby benzothiophene is desulfurized to 2-(2′ hydroxyphenyl)-ethan-1-al and an inorganic compound, possibly sulfite (Gilbert et al., 1998; Kim et al., 1999). This reaction corresponds to the dibenzothiophene desulfurization pathway discovered in *Rhodococcus erythropolis* IGTS8 (Oldfield et al., 1997, 1998).

The metabolic activity of *Gordonia* strains includes the ability of *Gordonia alkanivorans* to metabolize hexadecane (Kummer et al., 1999), *Gordonia nitida* (now a synonym of *Gordonia alkanivorans*) to utilize alkylpyridines, 3-ethylpyridine and 3-methylpyridine (Yoon et al., 2000c), and *Gordonia polyisoprenivorans* and *Gordonia westfalica* to degrade natural rubber substrates (Linos et al., 1999, 2000, 2002). Other poorly accessible carbon sources that can be degraded by gordoniae include *t*-butyl ether, methyl *t*-butyl either, *t*-amyl methyl ether, cyclic alkanes, and polycyclic aromatic hydrocarbons (Hernandez-Perez et al., 2001; Kästner et al., 1998; Koma et al., 2003). Members of the genus have been shown to metabolize butyl benzyl phthalates (Chaterjee and Dutta, 2003), fluoroanthene (Brito et al., 2006), and hazardous nitro compounds such as hexahydro-1,3,5-trinitro-1,3,5-triazine (hexogen), an explosive that is difficult to degrade (Gorontzy et al., 1994; Thompson et al., 2005).

An interesting soil isolate, designated *Gordonia* sp. strain TY-5, was found to utilize propane as a sole carbon and energy source (Kotani et al., 2003). These workers showed that the propane was oxidized to 2-propanol via subterminal oxidation by propane monoxygenase and further oxidized to acetone by secondary alcohol dehydrogenases. In a continuation of these studies, Kotani et al. (2007) found that the acetone was oxidized to methyl acetate by a novel Baeyer-Villiger monoxygenase (*acmA* gene product) and that the resultant methyl acetate was hydrolyzed to acetate and methanol by an esterase (*acmB* gene product). This study provided the first evidence for monoxygenase-dependent acetone oxidation and shed light on the poorly understood microbial pathway of acetone oxidation.

Gordoniae are a source of useful compounds such as carotenoids (De Miguel et al., 2000, 2001), lysine and some of its analogs (Kurimura et al., 1975), and gordonan, an acid, cell-aggregation-inducing polysaccharide (Kondo et al., 2000). "*Gordonia jacobaea*" MV-1 accumulates several carotenoids which include the ketocarotenoid *trans*-canthaxanthine and *trans*-astaxanthin. These compounds are currently produced by Hoffman-La Roche and have been approved by the Food and Drug Administration as food additives in poultry and fish feed. The generation of carotenoid-overproducing *Gordonia* strains could provide a valuable new biological source of these commercially important products. Such organisms may prove to be a valuable source of biosurfactants (Fusconi and Godinho, 2002; Nazina et al., 2003).

Genetics and molecular data. Gordonial genetics is in its infancy. However, the increasing interest in the metabolic activities of members of the genus has led to the generation of cloning vectors which allow the transfer of genes between different *Gordonia* species, the transfer of foreign genes from *Escherichia coli* to gordoniae, and the expression of these genes (Arenskötter et al., 2003; Arenskötter et al., 2004; Bröker et al., 2004). Gene transfer based on electroporation and conjugation has been demonstrated for *Gordonia alkanivorans* DSM 44187, "*Gordonia jacobaea"* MV-1 and MV-26, "*Gordonia nitida*" DSM 44499, *Gordonia rubripertincta* DSM 43197^{T} and DSM 46038, and *Gordonia terrae* DSM 43249^{T} (Arenskötter et al., 2003; Veiga-Crespo et al., 2006).

16S rRNA gene sequence similarities of *Gordonia* species range from 92.7% relatedness between the type strains of *Gordonia hydrophobica* and *Gordonia sinesedis* to 99.7% relatedness between those of *Gordonia aichiensis* and *Gordonia sputi*. The differences in the 16S rRNA gene sequences of *Gordonia* strains occur mainly in two hypervariable regions, i.e., between nucleotide positions 136 and 229, and 996 and 1028 using the numbering of the *Escherichia coli* K-12 16S rRNA gene sequence (Arenskötter et al., 2004). It is evident from comparative DNA–DNA relatedness data that the *Gordonia* species form distinct genomic species (Table 40). DNA–DNA relatedness data provided powerful support for the proposal that *Gordonia nitida* Yoon et al. 2000c be recognized as a later synonym of *Gordonia alkalinovorans* Arenskötter et al., 2005, as anticipated by Maldonado et al. (2003).

Greater resolution is found between *Gordonia* species in comparative analyses of *gyrB* sequences than in equivalent 16S rRNA gene sequences (Shen et al., 2006a, 2008). A comparison of *gyrB* protein sequences and corresponding 16S rRNA nucleotide sequences between *Gordonia* strains and representatives of *Corynebacterium xerosis* (66–70% against 71–72%), *Dietzia maris* (70–74% against 92–94%), *Nocardia brasiliensis* (75–79% against 94–95%), *Rhodococcus rhodochrous* (76–80% against 94–95%), *Skermania piniformis* (76–80% against 93–95%), *Tsukamurella paurometabola* (72–76% against 94–95%), and *Williamsia murale* (73–79% against 94–96%) illustrates this point (Shen et al., 2006b). It is evident, therefore, that *Gordonia* strains form a well-delineated phyletic line in the *gyrB* tree and can thereby be separated from other genera classified in the order *Corynebacteriales*.

Antibiotic sensitivity. Few studies have addressed the antibiotic susceptibility patterns of *Gordonia* strains and even then such work have been driven mainly by taxonomic considerations (Goodfellow et al., 1994; Goodfellow and Orchard, 1974; Kummer et al., 1999). However, this subject is of growing importance as some gordoniae are opportunistic human pathogens that are being isolated with increased frequency from patients and clinical materials. There is evidence that clinically significant gordoniae are highly susceptible to imidazole antifungal agents (Dabbs et al., 2003), and that bacteremias caused by *Gordonia* species can be effectively treated using a combination of aminoglycosides and penicillins (Riegel et al., 1996). The antibiotic sensitivity profiles of some *Gordonia* species are included in the species descriptions.

[a] Data taken from Brandão et al. (2001), Iida et al. (2005), Kageyama et al. (2006), Kim et al. (1999, 2000), Kummer et al. (1999), Le Roes et al. (2008), Linos et al. (2002), Mordarski et al. (1981), Riegel et al. (1994), Takeuchi and Hatano (1998), Yoon et al. (2000a), and Zakrzewska-Czerwinska et al. (1988).

Pathogenicity. Gordoniae are being isolated increasingly from clinical material (Blaschke et al., 2007; Iida et al., 2005; Kageyama et al., 2006; Klatte et al., 1994b; Tsukamura, 1971, 1978). *Gordonia bronchialis* and *Gordonia sputi* have been isolated from sputa of patients with pulmonary disease, bronchiectasis, and cavitary pulmonary tuberculosis (Gugnani et al., 1998; Klatte et al., 1994b; Tsukamura, 1971, 1978; Tsukamura and Yano, 1985). A nosocomial outbreak of sternal wound infections in patients following coronary artery bypass surgery (Herve et al., 1991) was attributed to *Gordonia bronchialis*, as were cases of bacteremia in patients with pulmonary sequestration (Sng et al., 2004). *Gordonia bronchialis* has been reported to cause breast abscesses (Werno et al., 2005) and *Gordonia sputi*, bacteremia (Riegel et al., 1996) and mediastinitis (Kuwahara et al., 1999); a *Gordonia* strain related to *Gordonia sputi* was implicated in a case of endocarditis of a young woman fitted with a central venous catheter (Lesens et al., 2000). *Gordonia polyisoprenivorans* has been reported to cause endocarditis (Verma et al., 2006) and septicemia in a bone marrow transplant patient (Kempf et al., 2004). The first reported case involving *Gordonia rubripertincta* was a lung infection of a young immunocompromised female where an initial diagnosis was confused with tuberculosis (Hart et al., 1988). Gordoniae, especially *Gordonia terrae*, have been reported to cause central venous catheter-related bacteremia (Buchman et al., 1992; Lesens et al., 2000; Pham et al., 2003), brain abscesses (Drancourt et al., 1994, 1997), and cutaneous infections (Lasker et al., 1992; Lesens et al., 2000; Martin et al., 1991; Zardawi et al., 2004), including a case of mycetoma of the hand (Bakker et al., 2004).

Infections caused by gordoniae are probably underestimated as a result of oversight or misidentification in diagnostic laboratories (Blanc et al., 2007; Gil-Sande et al., 2006). Gordoniae are relatively slow-growing bacteria hence isolation plates need to be incubated beyond the usual 48 h period used in diagnostic settings. Precise identification of *Gordonia* strains requires the application of chemotaxonomic and molecular systematic procedures (Goodfellow et al., 1998a, 1999; Nishiuchi et al., 2000; Patel et al., 2004; Steingrübe et al., 1997), as reliance on biochemical tests can lead to the assignment of gordoniae to other mycolic acid-containing genera, notably the genus *Rhodococcus* (Gil-Sande et al., 2006; Pham et al., 2003; Sng et al., 2004).

Improvements in the classification of the genus *Gordonia* are contributing to the recognition of new opportunistic pathogens. *Gordonia arai* was described for an organism isolated from sputum of a 48-year-old man with bacterial pneumonia (Kageyama et al., 2006), *Gordonia effusa* from a 74-year-old man with kidney dysfunction (Kageyama et al., 2006), and *Gordonia otitidis* from the ear discharge of a young woman with external otitis, and from a 60-year-old man with bronchitis (Iida et al., 2005). Gordoniae have not been implicated as disease agents of animals, apart from being associated with a case of mesenteric lymphadenitis of the ileum in a 6-year-old pig (Tsukamura et al., 1988).

Ecology. Gordoniae are widely distributed in the environment possibly because of their ability to metabolize a wide range of pollutants, many of which are toxic (Brandão et al., 2001; Dabbs, 1998). They have been isolated from soil (Kim et al., 2000; Luo et al., 2007; Maldonado et al., 2003; Shen et al., 2006a), mangrove and marine sediments (Brito et al., 2006; Colquhoun et al., 1998b), packing material of a biofilter used for biological odor abatement (Bendinger et al., 1995), industrial wastewater (Yoon et al., 2000a), wastewater treatment bioreactors (Kim et al., 2003; Yassin et al., 2007a), an oil shale spoil heap (Kim et al., 1999), clinical material (Drancourt et al., 1994; Kageyama et al., 2006; Richet et al., 1991; Tsukamura, 1971), and the intestinal contents of mammals (Brown et al., 1999).

Improvements in gordonial systematics facilitated the design, evaluation, and use of an oligonucleotide primer set to determine the presence, distribution, and taxonomic diversity of members of the genus *Gordonia* in soil samples (Shen and Young, 2005). The primers, designated G268F/G1096R, amplified a 829-bp stretch of 16S rRNA genes from authenticated members of the genus *Gordonia*, but not from representatives of other mycolic acid containing genera. The primer set was used to detect the presence of gordoniae in diverse soil samples. In addition, BOX-PCR analysis revealed the presence of genetic polymorphisms amongst a few *Gordonia* wild-type isolates.

Large numbers of gordoniae have been isolated from foaming activated sludge plants in diverse geographical locations (Goodfellow et al., 1996, 1998b; Soddell and Seviour, 1990; Stainsby et al., 2002). It is generally accepted that mycolic acids render cells sufficiently hydrophobic to allow them to accumulate on the surfaces of aeration tanks (Seviour and Blackall, 1999). Initially, *Gordonia amarae* (formerly *Nocardia amarae*) was implicated in foam formation (Blackall et al., 1988; Dhaliwal, 1979; Hiraoka and Tsumura, 1984; Lechevalier and Lechevalier, 1974; Sakai et al., 1983; Sezgin et al., 1988; Soddell et al., 1992), but it is now evident that many different mycolic acid containing actinomycetes are involved, including *Gordonia defluvii* (Soddell et al., 2006b) and *Millisia brevis* (Soddell et al., 2006b).

Oligonucleotide hybridization and antibody probes have been designed to identify and quantify mycolic acid-containing actinomycetes, gordoniae and *Gordonia amarae* in order to determine whether foaming levels can be linked to the numbers of foam-causing organisms (de los Reyes et al., 1997, 1998a, 1998b, 1998c; Oerther et al., 1999). Subsequently these studies established a cause-effect relationship between *Gordonia amarae* and foaming (de los Reyes and Raskin, 2002). These workers also determined *Gordonia* levels for foam formation and foam stability, but pointed out that such thresholds might be treatment-plant specific. Davenport et al. (2000) used quantitative fluorescent *in situ* hybridization to examine the relationships between foaming and the concentration of mycolic acid-containing actinomycetes in a 20 m^3 completely mixed activated sludge reactor. The concentration of the organisms needed to induce foaming was about 2×10^6 cells/ml or 4×10^{12} cells/m^2. Pagilla et al. (2002) showed that foaming problems in activated sludge are due to the production of biosurfactants by *Gordonia amarae* when hydrophobic substances such as hexadecane are present.

Mycolic acid antibodies that react with *Gordonia amarae* and related taxa may provide an effective means of detecting mycolic acid-containing actinomycetes in activated sludge foam (Iwahori et al., 2001). Immunochemical detection of representatives of mycolic acid-containing genera in enzyme-linked immunosorbent assays (ELISAs) indicated that the extent of the antibody reactions was related to the length of the mycolic acid chains in the walls of the marker organisms. In contrast, reactivity against Gram-stain-positive bacteria that lacked mycolic acids was negligible.

Gordonia strains can survive in polluted habitats under near starvation conditions (Acharya and Desai, 1997; Warhurst and Fewson, 1994). They are able to metabolize diverse hydrocarbons, including halogenated compounds, as well as numerous substituted aromatic compounds (Peczynska-Czoch and Mordarski, 1988; Tárnok, 1976; Warhurst and Fewson, 1994). Their ability to grow in highly polluted environments makes them attractive candidates for the selective removal of contaminants from commodity products and in bioremediation.

Enrichment and isolation procedures

Large numbers of gordoniae have been isolated on glucose-yeast extract agar plates (Gordon and Mihm, 1962a) supplemented with cycloheximide and incubated at 30°C for 14 d following inoculation with serially diluted samples taken from foaming activated sludge plants (Goodfellow et al., 1996b, 1998a). The gordoniae were recognized by their ability to form rough, grayish-pink dry colonies on the isolation plates. Initial characterization studies showed that most of the isolates formed new centers of taxonomic variation in the genus.

Gordoniae can be isolated from sputa and soils by plating chemically treated samples onto a selective medium (Tsukamura, 1971; Tsukamura et al., 1988). Sputum samples suspended in distilled water (25 ml) are added to an equal volume of NaOH (4%) and liquefied either by shaking at room temperature for 15–20 min or by incubation at 37°C for 30 min then inoculated onto Ogawa egg medium (Tsukamura, 1962) and incubated for 4–8 weeks. Similarly, soils (5 g) suspended in distilled water (25 ml) are shaken vigorously in a 300-ml Erlenmeyer flask at room temperature on a reciprocal shaker for 30 min; the resultant suspension is allowed to settle for 10 min when 15 ml of the supernatant is added to an equal volume of NaOH (8%), and the preparation shaken for 10 min prior to centrifugation at 500 × *g* for 15 min. The residue is suspended in 10 ml of a 1% NaH_2PO_4 solution, and 0.002 ml is added to Ogawa egg medium slants that are incubated for 4–8 weeks.

Colonies growing on Ogawa egg medium slants are subcultured to fresh slopes supplemented with sodium salicylate (0.5 mg/ml), which inhibits *Mycobacterium tuberculosis* (Tsukamura, 1962). Smears, prepared from colonies growing on the slants supplemented with sodium salicylate after incubation at 37°C for 3 weeks, are stained by the Ziehl–Neelsen procedure and examined by light microscopy. Slightly acid-fast, rod-shaped bacteria are typical of gordoniae; those strongly acid-fast can be taken to be mycobacteria. Gordoniae form rough pinkish or reddish colonies on Ogawa egg slants plugged with cotton wool.

Suitable media for the isolation of *Gordonia amarae* include Czapek's agar supplemented with yeast extract (Higgins and Lechevalier, 1969) and glycerol agar (Gordon and Smith, 1953); macroscopically visible colonies are evident within 5–7 d at 30°C (Lechevalier et al., 1976; Lechevalier and Lechevalier, 1974). Similarly, *Gordonia rubripertincta* has been isolated on Munz and Winogradsky's nitrate agars supplemented with paraffin (Nesterenko et al., 1978a), *Gordonia lacunae* on yeast

extract-malt extract agar following incubation for 5 d at 30°C (Le Roes et al., 2008), *Gordonia otitidis* on blood agar plates incubated for 7 d at 37°C (Iida et al., 2005), *Gordonia hirsuta* on antibiotic sulfonamide sensitivity test agar (Klatte et al., 1996), and *Gordonia sihwensis* on succinate mineral agar plates incubated at 28°C for 7 d (Kim et al., 2003). *Gordonia defluvii* strains were isolated, by micromanipulation, from activated sludge foams, as described by Soddell and Seviour (1998).

A range of novel gordoniae have been recovered from diverse environmental samples by enrichment culture, as exemplified by the isolation of *Gordonia alkanivorans* (Kummer et al., 1999; Yoon et al., 2000c), *Gordonia amicalis* (Kim et al., 2000), *Gordonia desulfuricans* (Kim et al., 1999), *Gordonia namibiensis* (Brandão et al., 2001), and *Gordonia paraffinivorans* (Xue et al., 2003).

Maintenance procedures

A convenient method for short-term storage can be achieved by serial transfer every 2 months from appropriate media, such as modified Bennett's (Jones, 1949) and glucose-yeast extract (Gordon and Mihm, 1962a) agar slopes with storage between transfers at 4°C. Long-term storage involves lyophilization, or storage in liquid nitrogen or frozen glycerol suspensions. For lyophilization, biomass is suspended in a medium such as glucose serum (7.5%, w/v) or skimmed milk supplemented with glucose (7.5%, w/v). For preservation in liquid nitrogen, organisms are inoculated onto a suitable medium in small tubes until sufficient growth is visible. These preparations are sealed with cotton wool plugs dipped in liquid paraffin wax and placed in a liquid nitrogen container. Glycerol suspensions prepared by scraping growth from heavily inoculated agar plates are used to make heavy suspensions in aqueous glycerol (3 ml), held in small vials, which are stored at –20°C (Wellington and Williams, 1978).

Differentiation of the genus *Gordonia* from other genera

Gordonia strains can be differentiated from members of other genera classified in the order *Corynebacteriales* by using a combination of chemotaxonomic and morphological markers (Table 29) and by partial sequencing of ribosomal protein AT-L30 (Ochi, 1995). Carbon utilization tests (Biotype 100 strips) may also be of value in distinguishing between members of the genera *Dietzia, Gordonia*, and *Rhodococcus* (Bizet et al., 1997). Representatives of these taxa have been separated by mycolic acid profiles generated by capillary gas chromatography and mass spectrometry (Nishiuchi et al., 2000). Partial 16S rRNA gene sequences have been used for the identification of clinically significant aerobic actinomycetes belonging to taxa that include the genera *Gordonia, Nocardia*, and *Tsukamurella* (Patel et al., 2004), as has DNA amplification and restriction endonuclease analysis (Steingrübe et al., 1997).

Taxonomic comments

Michio Tsukamura proposed the genus *Gordona* for slightly acid-fast actinomycetes isolated from soil and sputa of patients with pulmonary disease. The founder members of the genus, *Gordonia bronchialis, Gordonia rubra*, and *Gordonia terrae*, were subsequently reclassified in the revised (Tsukamura, 1974) and redescribed genus *Rhodococcus* (Goodfellow and Alderson, 1977) though it soon became apparent that this taxon was markedly heterogeneous. The etymologically correct name, *Gordonia*, was introduced by Stackebrandt et al. (1997).

Rhodococcal species were eventually assigned to two aggregate groups based on the discontinuous distribution of key chemical markers (Goodfellow, 1998). Strains previously classified in the genus *Gordonia* contained mycolic acids with between 48 and 66 carbon atoms and major amounts of dihydrogenated menaquinones with nine isoprene units, the remaining organisms were characterized by shorter chain mycolic acids (34–52 carbon atoms) and dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue (Alshamaony et al., 1976b; Collins et al., 1977, 1985). The validity of these taxa was underpinned by results from antibiotic sensitivity tests (Goodfellow and Orchard, 1974), delayed skin reactions in sensitized guinea pigs, and by polyacrylamide gel electrophoresis of cell extracts (Hyman and Chaparas, 1977). The subsequent discovery that the two aggregate taxa were distinct phylogenetically led Stackebrandt et al. (1988) to revive the genus *Gordona* for organisms classified as *Rhodococcus bronchialis, Rhodococcus rubropertincta, Rhodococcus sputi*, and *Rhodococcus terrae. Rhodococcus obuensis* Tsukamura (1982a) was reduced to a subjective synonym of *Rhodococcus sputi* primarily on the basis of DNA–DNA relatedness data (Zakrzewska-Czerwinska et al., 1988).

The genus *Gordonia* contains 26 validly published species which form a well delineated clade within the evolutionary radiation encompassed by mycolic acid-containing actinomycetes (Goodfellow and Maldonado, 2006; Le Roes et al., 2008). The status of most of these species is supported by a wealth of genotypic and phenotypic data (Brandão et al., 2001; Goodfellow and Alderson, 1977; Goodfellow et al., 1991a; Luo et al., 2007; Soddell et al., 2006b; Tsukamura, 1974). Indeed, DNA–DNA relatedness data show that most *Gordonia* species, including *Gordonia amarae, Gordonia araii, Gordonia bronchialis, Gordonia desulfuricans, Gordonia namibiensis*, and *Gordonia westfalica* are well delineated genomic species (Brandão et al., 2001; Kageyama et al., 2006; Kim et al., 1999; Linos et al., 2002; Mordarski et al., 1976, 1980; Zakrzewska-Czerwinska et al., 1988). It seems likely that additional gordonial species will be delineated as there is evidence that the genus is underspeciated (Goodfellow et al., 1996, 1998a; Schuppler et al., 1995).

Differentiation of species of the genus *Gordonia*

Gordonia species can be distinguished using a combination of molecular sequence (Figure 93), DNA–DNA relatedness (Table 40), and phenotypic data (Table 41). Preliminary evidence suggests that fatty acid analyses (McNabb et al., 1997), Curie-point pyrolysis mass spectrometry (Goodfellow et al., 1996, 1998a) and rapid enzyme tests based on the fluorophores 7-amino-4-methylcoumarin and 4-methylumbelliferone (Goodfellow et al., 1991a) may provide a reliable means of distinguishing between *Gordonia* species. PCR-restriction enzyme analysis of the 439-bp Telenti fragment of the 65 *hsp* gene and carbon utilization tests have provided reliable data for assigning clinically significant gordoniae to the species level (Patel et al., 2004).

List of species of the genus *Gordonia*

1. **Gordonia bronchialis** (Tsukamura 1971) Stackebrandt, Smida and Collins 1989, 371[VP] (*Gordonia bronchialis* Tsukamura 1971, 22; basonym: *Rhodococcus bronchialis* Tsukamura 1971, 1974)

bron. chi′a.lis. L. pl. n. *bronchia* the bronchial tubes; L. fem. suff. -*alis* suffix used with the sense of pertaining to; N.L. fem. adj. *bronchialis* pertaining to the bronchi, coming from the bronchi.

Rod–coccus life cycle. Rough brownish colonies formed on egg media, glucose-yeast extract agar, and Sauton's agar. Synnemata composed of vertically arranged coalescing filaments are formed on the surface of colonies after 12–18 h of incubation. Grows between 20°C and 40°C, but not 10°C or 45°C.

Acetamidase, nicotinamidase, pyrazinamidase, and urease-positive, but negative for allantoinase, benzamidase, isonicotinamidase, malonamidase, salicylamidase, and succinamidase. Acid phosphatase and β-esterase-positive, but negative for α-esterase and β-galactosidase.

Acid is produced from glucose, inositol, maltose, mannose, and trehalose, but not from arabinose, galactose, raffinose, rhamnose, sorbitol, or xylose.

Grows on acetamide, *iso*-butanol, *p*-cresol, ethanol, glycerol, *p*-hydroxybenzoic acid, inositol, maltose, mannose, propanol, propylene glycol, benzoate, sodium gluconate, sodium lactate, sodium malate, sodium pyruvate, sodium sebacate, sorbitol, sodium succinate, sucrose, testosterone, and trehalose as sole carbon sources, but not on *m*-hydroxybenzoic acid, rhamnose, or L-tyrosine. L-glutamate, isonicotinamide, L-methionine, nicotinamide, pyrazinamide, L-serine, succinamide, and urea are used as sole nitrogen sources, but not benzamide or nitrite. Acetamide, D-alanine, and L-glutamate are used as sole sources of carbon and nitrogen, but not L-alanine, L-asparagine, benzamide, monoethanolamine, L-serine, L-threonine, or trimethylenediamine.

Resistant to crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol, (0.3%, v/v), picric acid (0.2%, w/v), sodium aminosalicylate (0.2%, w/v), sodium azide (0.02%, w/v), and sodium chloride (7%, w/v). Resistant to (µg per ml) neomycin (4), oleandomycin (32), and vancomycin (4), but sensitive to chlortetracycline (4), fluorouracil (5), gentamicin (8), mitomycin C (5), and rifampin (8).

Mycolic acids have 54–66 carbon atoms. The major fatty acids are $C_{16:0}$ (19.6%), $C_{18:1}$ ω9*c* (13.3%) and 10-methyl $C_{18:0}$ ω9*c* (25.4%). The predominant menaquinone is MK-9(H_2).

Source: sputum of patients with pulmonary disease.

DNA G+C content (mol%): 63–65 (T_m).

Type strain: strain Tsukamura 3410, ATCC 25592, CCUG 22989, CCUG 34956, CIP 100847, DSM 43247, NBRC 16047, JCM 3198, JCM 3231, LMG 5355, KCC A-0198, NCTC 10667, VKM Ac-956.

Sequence accession no. (16S rRNA gene): X79287, X75903.

Sequence accession no. (gyrB): AY972059.

2. **Gordonia aichiensis** (Tsukamura 1982a) Klatte, Rainey and Kroppenstedt 1994b, 772[VP] (*Rhodococcus aichiensis* Tsukamura 1983, 896)

ai.chi.en′sis. N.L. fem. adj. *aichiensis* belonging to Aichi Prefecture, Japan from where the organism was isolated.

Rod–coccus life cycle. Rough pinkish or orange colonies are formed on egg media. Grows at 28°C and 42°C, but not at 45°C.

Positive for acetamidase, nicotinamidase, pyrazinamidase, urease, and valine arylamidase, but negative for allantoinase, benzamidase, isonicotinamidase, salicylamidase, and succinamidase. Positive for acid phosphatase, but negative for arylsulfatase, α- and β-esterase, and β-galactosidase.

Grows on fructose, glucose, mannose, sucrose, trehalose, *n*-butanol, ethanol, *iso*-butanol, *n*-propanol, sodium acetate, sodium citrate, sodium fumarate, sodium malate, sodium pyruvate, and sodium succinate as sole carbon sources, but not on arabinose, galactose, *meso*-inositol, mannitol, rhamnose, sorbitol, xylose, 1,3-, 1,4-, or 2,3-butylene glycol, propylene glycol, sodium benzoate, or sodium malate. Uses acetamide, glutamate, and monoethanolamine as sole sources of carbon and nitrogen.

Resistant to picric acid (0.2%, w/v), sodium nitrite (0.1%, w/v), and sodium salicylate (0.1%, w/v), but not to 5-fluorouracil (20 µg per ml), or mitomycin C (5 µg per ml).

Mycolic acids have 56–66 carbon atoms and up to 6 double bonds. Major fatty acids are $C_{16:1}$ *cis*9 (17.7%); $C_{16:0}$ (36.0%), $C_{18:1}$ *cis*9 (5.5%), and 10-methyl $C_{18:0}$ (23.0%). The predominant menaquinone is MK-8(H_2); minor amounts of MK-8(H_2) are also produced. The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: human sputum.

DNA G+C content (mol%): 65 (T_m).

Type strain: Tsukamura E 9028, ATCC 33611, CIP104184, DSM 43978, NBRC 160146, JCM 6046, NRRL B-16934.

Sequence accession no. (16S rRNA gene): X80633.

Sequence accession no. (gyrB): gy10795.

3. **Gordonia alkanivorans** Kummer, Schumann and Stackebrandt 1999, 1521[VP] (*Gordonia nitida* Yoon, Lee, Kang, Takeuchi, Shin, Lee, Kang and Park 2000c, 1209[VP])

al.ka.ni.vo′rans. N.L. n. *alkanum* saturated aliphatic hydrocarbon; L. v. *vorare* to eat; N.L. part. adj. *alkanivorans*, alkane-devouring.

Non-acid-fast, regular rod-shaped cells (0.5–0.9 × 1.0–2.3 µm) occur singly, in pairs, small clusters, in V-shape arrangements, or as short chains. Rod–coccus life cycle. Colonies orange to orange red. Colony morphology either convex and smooth or rough and flat with irregular margins. Grows at 13–40°C, but not at 5° or 42°C.

Acid is formed from fructose, glycerol, mannitol, sucrose, and sorbitol, but not from galactose, glucose, mannose, rhamnose, or salicin.

Acetate, *cis*-aconitate, benzoate, citrate, formate, malate, succinate, propionate, and pyruvate are used as sole carbon sources, but not lactate, oxalate, or tartrate.

Susceptible to (µg per ml) ampicillin (10), chloramphenicol (30), ciprofloxacin (5), gentamicin (10), kanamycin (30), neomycin (30), nitrofuran (100), oxytetracycline

(30), rifampin (30), streptomycin (10), and sulfonamide (250); weakly susceptible to erythromycin (15), oxacillin (5), penicillin G (10 IU), and polymyxin B (300 IU), but resistant to lincomycin (2).

Mycolic acids have 47–58 carbon atoms. The major fatty acids are $C_{16:0}$ (44.0%), $C_{18:1}$ ω9*c* (13%), and 10-methyl $C_{18:0}$ (28.0%). The predominant isoprenologue is MK-9(H_2); minor amounts of MK-8(H_2) are also produced.

Source: contaminated soil sample taken from the site of a former tar factory in Rositz, Germany.

DNA G+C content (mol%): 67–68 (HPLC).

Type strain: HKI 0136, CIP 106363, DSM 44369, NBRC 16433, JCM 10677.

Sequence accession no. (16S rRNA gene): Y18054.

Sequence accession no. (gyrB): ABO75553.

4. **Gordonia amarae** (Lechevalier and Lechevalier 1974) Klatte, Rainey and Kroppenstedt 1994b, 771[VP]. (*Nocardia amarae* Lechevalier and Lechevalier 1974, 286).

a.ma′ra.e. Gr. n. *amara* trench, conduit, channel; here a sewage duct; N.L. gen. n. *amarae* of a sewage duct.

Partially acid-fast actinomycete which forms moderately branching substrate hyphae that grow into agar media and do not fragment in undisturbed cultures. Aerial hyphae visible microscopically. Convoluted white to tannish colonies with filamentous margins are formed on standard media. Grows at 23–37°C, but not at 10° or 40°C.

Degrades Tweens 20, 40, and 60, but not casein, elastin, or gelatin.

Acid is produced from fructose, glucose, glycerol, *meso*-inositol, maltose, mannitol, mannose, rhamnose, salicin, sucrose, and trehalose, but not from L-arabinose, cellobiose, galactilol, galactose, glucitol, lactose, melibiose, α-methyl-D-glucoside, β-methyl-D-xyloside, raffinose, or xylose.

Grows on ethanol, fructose, glycerol, maltose, mannitol, rhamnose, salicin, sucrose, trehalose, sodium acetate, sodium adipate, sodium fumarate, sodium gluconate, sodium lactate, sodium malate, sodium pimelate, sodium propionate, sodium pyruvate, sodium sebacate, and sodium succinate as sole carbon sources, but not on acetamide, L-arabinose, benzamide, *p*-cresol, *m*-hydroxybenzoate, lactose, glucitol, melezitose, raffinose, xylose, sodium benzoate, sodium citrate, sodium oxalate, sodium tartrate, testosterone, or L-tyrosine. Does not use acetamide, D-alanine, L-alanine, L-asparagine, L-serine, L-threonine, or trimethylenediamine as sole carbon and nitrogen sources.

Susceptible to lysozyme, penicillin (10 IU), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), and sodium chloride (5% and 7%, w/v), but not to crystal violet (0.0001% and 0.001%, w/v), phenol (0.01%, w/v), or sodium azide (0.01%, w/v). Resistant to (μg per ml) rifampin (8), but is sensitive to chlortetracycline (4), gentamicin (16), neomycin (4), oleandomycin (32), penicillin G (32), and vancomycin (4).

Mycolic acids have 46–56 carbon atoms and up to 3 double bonds. The major fatty acids are $C_{16:0}$ (28.6%), $C_{18:1}$ ω9*c* (19.3%), and 10 methyl $C_{18:0}$ (21.8%). The predominant isoprenologue is MK-9(H_2). The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: foam formed on the surface of aeration tanks in activated-sludge sewage-treatment plants.

DNA G+C content (mol%): 60–66 (T_m).

Type strain: SE6, ATCC 27808, CIP 104501, DSM 43376, DSM 43392, DSM 43587, HAMBI 2282, NBRC 15530, JCM 3171, KCC A-0171, NCIMB 11222, NRRL B-8176, NRRL B-16281, VKM Ac-801.

Sequence accession no. (16S rRNA gene): X80635.

Sequence accession no. (gyrB): AB014105.

5. **Gordonia amicalis** Kim, Brown, Oldfield, Gilbert, Iliarionov and Goodfellow 2000, 2033[VP]

am.i.ca′lis. L. fem. adj. *amicalis* pertaining to friendship.

Slightly acid–alcohol-fast actinomycete which forms short rods and coccoid elements. Red colonies are formed on modified Bennett's and peptone-yeast extract agars. Grows at 10–40°C, and within the pH range 5.5–10.0.

Arbutin, glycerol, sodium adipate, sodium fumarate, sodium propionate, and sodium salicylate are used as sole carbon sources, but not D-arabinose, betaine, *N*-acetyl-D-glucosamine, sodium oxalate, or 1-propanol.

Grows in the presence of oleic acid (0.8%, v/v) and zinc chloride (0.001%, w/v).

Mycolic acids have 48–58 carbon atoms with C_{52}, C_{54}, and C_{56} as the main components. The predominant menaquinone is MK-9(H_2), but substantial amounts of MK-8(H_2) are also produced.

Source: garden soil, near Perm, Russia.

DNA G+C content (mol%): 64.2 (HPLC).

Type strain: IEGM, CCUG 48822, DSM 44461, KCTC 9899, KCTC 9940, JCM 11271, NBRC 100051.

Sequence accession no. (16S rRNA gene): AF101418.

Sequence accession no. (gyrB): AY972057.

6. **Gordonia araii** Kageyama, Iida, Yazawa, Kudo, Suzuki, Koga, Scuto, Inagawa, Wada, Kroppenstedt and Mikami 2006, 1820[VP]

a.rai′i. N.L. gen. masc. n. *araii* of Arai, to honor Tadashi Arai, a Japanese microbiologist, for his valuable contributions to microbial taxonomy and secondary metabolites research.

Slightly acid-fast, short elementary branching hyphae fragment into rod and coccoid-like elements. Rough colonies (1.5–3.5 mm) with irregular margins are formed after 7 d at 30°C on MMII medium. Colonies are white, becoming beige. Soluble pigments are not formed.

Glucose, ribose, and sucrose are used as sole carbon sources, but not *N*-acetyl-D-glucosamine, acetamide, aconitol, L-alanine, arabinose, L-aspartate, erythritol, galactose, 4-hydroxybenzoate, *myo*-inositol, L-leucine, maltose, mannose, 2-oxoglutarate, putrescine, sodium quinate, sodium glutarate, sodium succinate, sorbitol, turanose, or L-valine.

Mycolic acids with 64–70 carbon atoms. The major fatty acids are $C_{14:0}$, $C_{16:1}$ *cis*9, $C_{16:0}$, $C_{18:1}$ *cis*9, $C_{18:0}$, and 10-methyl-$C_{18:0}$. The predominant menaquinone is MK-9(H_2).

Source: a patient with kidney dysfunction.

DNA G+C content (mol%): not determined.

Type strain: IFM 10211, DSM 44811, JCM 12131, NBRC 100433.

Sequence accession no. (16S rRNA gene): AB162800.

7. **Gordonia defluvii** Soddell, Stainsby, Eales, Seviour and Goodfellow 2006b, 2267[VP]

de.flu'vi.i. L. gen. n. *defluvii* of sewage.

Slightly acid–alcohol-fast, slowly growing actinomycete which shows acute-angled and right-angled branching. Non-pigmented colonies with filamentous margins and abundant aerial hyphae are formed on glucose-yeast extract agar. Diffusible pigments are not produced. Grows at pH 5–8 and 15–30°C, albeit weakly at the higher end of this range.

Esterase lipase (C_8), leucine aminopeptidase, and β-glucosidase-positive, but negative for alkaline phosphatase, chymotrypsin, α-fucosidase, α- and β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, trypsin, and valine aminopeptidase. Positive for catalase and phosphatase, but negative for *m*- and *p*- nitrophenol oxidases.

Degrades Tween 20, but not casein or elastin.

Pyruvate is used as a sole carbon source, but not arabinose, fructose, galactose, maltose, mannose, melezitose, rhamnose, salicin, or sorbitol (all at 0.1% w/v), or acetamide, benzamide, sodium benzoate, sodium butyrate, sodium citrate, *p*-cresol, gluconate, *m*- and *p*-hydroxybenzoic acid, sodium lactate, sodium malate, sodium octanoate, sodium oxalate, sodium pimelate, sodium propionate, sodium sebacate, sodium succinate, sodium tartrate, testosterone, or tyrosine (all at 0.01% w/v).

Does not grow in the presence of crystal violet (0.001%, w/v), phenol (0.01%, w/v), phenol ethanol (0.03%, v/v), sodium azide (0.01%, w/v), sodium chloride (5%, w/v), or penicillin (10 IU).

The methyl esters of the mycolic acids have the same Rf value on one-dimensional thin-layer-chromatography as those of *Gordonia bronchialis* DSM 43247[T]. The major fatty acid components are oleic ($C_{18:1}$; 35%), palmitic ($C_{16:0}$; 21%), palmitoleic ($C_{16:1}$; 18%), and tuberculostearic (9%) acids. The predominant menaquinone is MK-9(H_2), and smaller amounts of MK-8(H_2) are also produced. The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: a foam sample taken from an activated sludge plant at Brimbank Park, Victoria, Australia.

DNA G+C content (mol%): 63.1 (HPLC).

Type strain: J4, DSM 44981, NCIMB 14149.

Sequence accession no. (16S rRNA gene): AY650267.

8. **Gordonia desulfuricans** Kim, Brown, Oldfield, Gilbert and Goodfellow 1999, 1847[VP]

de.sul.fu'ri.cans. L. pref. *de* from; L. n. *sulfur* sulfur; N.L. part. adj. *desulfuricans* reducing sulfur compounds.

Slightly acid–alcohol-fast actinomycete which forms short rods and coccoid elements. Rough pinkish colonies are formed on modified Bennett's and peptone-glucose-yeast extract agars. Neither aerial hyphae nor diffusible pigments are produced.

D-Arabinose, glycerol, sodium propionate, and sodium salicylate are used as sole carbon sources.

Grows in the presence of adenine (0.25%, w/v), oleic acid (0.8%, w/v), and zinc chloride (0.001%, w/v), but is sensitive to picric acid (0.3%, w/v).

Mycolic acids have 56–64 carbon atoms with up to 3 double bonds. The predominant menaquinone is MK-9(H_2), and minor amounts of MK-8(H_2) are also produced.

Source: a soil sample collected adjacent to an oil shale spoil heap near a disused mine located at West Calder, West Lothian, Scotland.

DNA G+C content (mol%): 63–65 (HPLC).

Type strain: 213E, DSM 44462, JCM 11762, NBRC 100010, NCIMB 40816.

Sequence accession no. (16S rRNA gene): AF 101416.

Sequence accession no. (gyrB): gy12627.

9. **Gordonia effusa** Kageyama, Iida, Yazawa, Kudo, Suzuki, Koga, Saito, Inagawa, Wada, Kroppenstedt and Mikami 2006, 1820[VP]

ef.fu'sa. L. fem. adj. *effusa*, poured out, extensive, vast, broad, wide, referring to the spreading colonial growth.

Slightly acid-fast, short elementary hyphae fragment into rod- and coccoid-like elements. Rough colonies (3.0–5.0 mm) with irregular margins are formed after 7 d at 30°C on MMII medium. Colonies are white, becoming beige. Soluble pigments are not formed.

N-Acetyl-*N*-glucosamine, L-alanine, L-aminobutyrate, L-aspartate, putrescine, sodium citrate, sodium succinate, turanose, and L-valine are used as sole carbon sources, but not acetamide, arabitol, galactose, sodium glutarate, 4-hydroxybenzoate, *myo*-inositol, L-leucine, 2-oxoglutarate, sodium quinate, L-rhamnose, or D-ribose.

Mycolic acids have 56–64 carbon atoms. The major fatty acids are $C_{14:0}$, $C_{15:0}$, $C_{16:0}$, $C_{17:0}$, $C_{18:0}$, and 10-methyl $C_{18:0}$. The predominant menaquinones are MK-9(H_8) and MK-9(H_6), and a small amount of MK-9(H_4) is also produced.

Source: a patient with pulmonary disease.

DNA G+C content (mol%): not determined.

Type strain: IFM 10200, DSM 44810, JCM 12130, NBRC 100432.

Sequence accession no. (16S rRNA gene): AB162799.

10. **Gordonia hirsuta** Klatte, Kroppenstedt, Schumann, Altendorf and Rainey 1996, 879[VP]

hir.su'ta. L. fem. adj. *hirsuta* shaggy, rough, referring to the rough surfaces of colonies.

Non-acid-fast rods. White to light yellow colonies with irregular margins and flat, rough surfaces are formed on various media.

Catalase-positive and oxidase-negative. Hydrolyzes pNP-phosphorylcholine, but not 2-deoxythymidine -5′-pNP-phosphate, or pNP-β-D-xyloside.

Galactose, *meso*-inositol and 2-oxoglutarate are metabolized, but not acetamide, *N*-acetyl-D-glucosamine, L-alanine, 4-aminobenzoate, D-arabinose, L-aspartate, D-glucosamine acid, 3- and 4- hydroxybenzoate, 2-hydroxyvaline, phenylacetic acid, sodium benzoate, sodium citrate, sodium gluconate, sodium pimelate, sodium succinate, putrescine, sodium quinate, ribose, rhamnose, ribose, L-serine, sucrose, turanose, tyramine, L-proline, or L-valine.

Mycolic acids have 60–64 carbon atoms with C_{62} and C_{64} as the main components. The major fatty acids are $C_{16:1}$

*cis*10 (16%), $C_{16:0}$ (30%), $C_{16:1}$ *cis*9 (30%), and 10-methyl $C_{18:0}$ (17%). MK-9(H_2) is the predominant menaquinone. The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: packing material (tree bark compost) of a large-scale biofiller used for deodorization of animal-rending emissions.

DNA G+C content (mol%): 69 (HPLC).

Type strain: K718a, ATCC 700255, CCUG 38498, CIP 105097, DSM 44140, NBRC 16056, JCM 10105.

Sequence accession no. (16S rRNA): X93485.

Sequence accession no. (gyrB): gy10796.

11. **Gordonia hydrophobica** Bendinger, Rainey, Kroppenstedt, Moorman and Klatte 1995, 547[VP]

hy.dro.pho′bi.ca. Gr. n. *hydro* water, Gr. n. *phobos* fear, dread; L. fem. suff. *-ica* suffix used with the sense of pertaining to; N.L. fem. adj. *hydrophobica* water avoiding, related to hydrophobic.

Non-acid-fast actinomycete which forms long rods (2–3 μm) and shows a rod–coccus life cycle. White to tannish colonies are formed on standard media. Colonies may be rough and flat with irregular margins. On primary isolation, colonies may be convex with entire or undulate margins and a smooth surface.

Cleaves pNP-phosphorylcholine and 2-deoxythymidine-5′-pNP-phosphate, but not pNP-β-D-xyloside. Does not degrade adenine, or produce acid from sucrose aerobically or anaerobically.

Galactose, leucine, sodium citrate, sodium propionate, and sodium succinate are used as sole carbon sources, but not 5-aminovaleric acid, arabinose, aspartic acid, asparagine, gluconic acid, *meso*-inositol, ribose, L-rhamnose, or sodium adipate. Grows on readily volatile carbonyl compounds: butanone, 2- and 3-methylbutanal, 4-methyl-2-pentanone, methylpropanal, and 2-pentanone when added as sole carbon sources into sealed agar slope cultures.

Mycolic acids have 54–62 carbon atoms with C_{58} and C_{60} as the main components. The major fatty acids are $C_{16:1}$ *cis*10 (13%), $C_{16:0}$ (27%), $C_{18:1}$ *cis*9 (14%), and 10-methyl $C_{18:0}$ (26%). The predominant menaquinone is MK-9(H_2); minor amounts of MK-8(H_2) are also produced.

Source: a packing material (tree bark compost) of biofillers for deodorization of animal rendering emissions.

DNA G+C content (mol%): 69 (HPLC).

Type strain: 1610/1b, ATCC 700089, CCUG 38497, CIP 104672, DSM 44015, NBRC 16057, JCM 10086.

Sequence accession no. (16S rRNA gene): X87340.

Sequence accession no. (gyrB): gy10560.

12. **Gordonia lacunae** Le Roes, Goodwin and Meyers (2008)

la. cu′ na.e. L. gen. fem. n. *lacunae* of a pool, pond, intended to mean of or from a lagoon, the source of the isolate.

Partially acid-fast actinomycete which forms elementary branching hyphae that fragment into rod-shaped elements. Pink orange colonies are formed on yeast extract-malt extract agar. Colonies are yellow orange when cultivated in the dark. Light yellow brown colonies are produced on inorganic salts-starch agar. Melanin pigments are not formed on either peptone-yeast-extract, or tyrosine agars. Grows at 10°C (weak) and 37°C, and at pH 4.3.

Lecithin activity is observed on egg yolk agar. Produces hydrogen sulfide. Degrades guanine (weak), but not gelatin, hippurate, pectin, or xylan.

Adonitol (weak), DL-α-amino-*n*-butyrate, L-arabinose, fructose, galactose (weak), glucose, L-hydroxyproline, *meso*-inositol (weak), lactose, mannitol, mannose, melezitose (weak), melibiose (weak), raffinose (weak), salicin (weak), sodium acetate (weak), sodium citrate, sucrose, trehalose, xylitol, and xylose are used as sole carbon sources but not inulin, or ribose. L-Arginine, L-cysteine, L-histidine, L-methionine, potassium nitrate, L-serine, and L-valine are used as sole nitrogen sources with weak utilization of DL-α-amino-*n*-butyric acid, L-hydroxyproline, and L-phenylalanine.

Grows in the presence of phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), sodium azide (0.02%, w/v), and sodium chloride (7%, w/v). Resistant to (μg per ml) cephaloridine (100), kanamycin (100), oleandomycin (100), penicillin G (10 i.u. per ml), rifampin (50), tobramycin (50), and vancomycin (50), but susceptible to gentamicin (100), lincomycin (100), neomycin (50), and streptomycin (100).

Bioautographic analysis of organic solvent extracts of the cell mass shows weak antibiosis against *Mycobacterium aurum* A+ and *Mycobacterium smegmatis* LR222, but no activity against *Mycobacterium tuberculosis* H37Rv[T].

Whole-organism hydrolysates contain arabinose, galactose, glucose, and ribose. Mycolic acids have been detected by one-dimensional thin layer chromatography.

Source: sand taken from an estuary in Plettenberg Bay, Western Cape Province, South Africa.

DNA G+C content (mol%): not determined.

Type strain: BS2, DSM 45085, JCM 14873, NRRL B-24551.

Sequence accession no. (16S rRNA gene): EF151959.

Sequence accession no. (gyrB): EF608480.

13. **Gordonia malaquae** Yassin, Shen, Hupfer, Arun, Lai, Rekha and Young 2007a, 1067[VP]

mal.a′qua.e. L. adj. *malus* bad; L. n. *aqua* water, N. L. gen. n. *malaquae* of bad water, effluent.

Non-acid–alcohol-fast actinomycete which forms rod- and coccoid-like elements. Smooth cream colored colonies formed on agar media. Grows between 22–37°C, but not at 42°C.

Degrades testosterone, but not casein, elastin, gelatin, or guanine. Assimilates acetate, 2, 3 butanediol, citrate, glucose, paraffin, sucrose, trehalose, and xylose as carbon sources, but not adonitol, adipate, *iso*-amyl alcohol, L-arabinose, cellobiose, *meso*-erythritol, galactose, gluconate, *m*- and *p*-hydroxybenzoate, *myo*-inositol, lactate, lactose, maltose, mannitol, melezitose, 1,2-propandiol, raffinose, rhamnose, or sorbitol. L-Alanine, L-proline and L-serine are used as sole carbon and nitrogen sources, but not acetamide, arginine, gelatin, or ornithine.

Mycolic acids have been detected by one-dimensional thin layer chromatography. The major fatty acids are $C_{16:0}$ (40.0%), $C_{17:0}$ (18.5%), and 10-methyl $C_{18:0}$ (13.2%). The predominant menaquinone is MK-9(H_2); minor amounts of MK-8(H_2) are also produced. The cellular polar lipid composition includes diphosphatidylglycerol, phos-

phatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: sludge taken from a wastewater sediment plant.

DNA G+C content (mol%): not determined.

Type strain: IMMIB WWCC-22, CCUG 53555, DSM 45064, JCM 14874.

Sequence accession no. (16S rRNA gene): AM406674.

14. **Gordonia namibiensis** Brandão, Maldonado, Ward, Bull and Goodfellow 2001, 514[VP]

na.mi.bi.en′sis. N.L. fem. adj. *namibiensis* of or belonging to Namibia, the origin of the soil sample from which the organism was isolated.

Slightly acid–alcohol-fast actinomycete which forms short rods and coccoid elements. Orange or red-pink colonies are formed on glucose-yeast extract agar. Neither aerial hyphae nor diffusible pigments are produced. Grows at 20–40°C, and pH 4.5–9.5.

D-Arabinose, dulcitol, *meso*-erythritol (weak), ethanol, D-fucose, fructose, galactose, glycerol (weak), glycogen, glucose, *meso*-inositol, lactose, maltose, mannose, melezitose, melibiose, α-methyl-D-glucoside, raffinose, ribose, trehalose, xylose, xylitol (all at 1% w/v), sodium acetate, sodium fumarate, sodium gluconate, *m*- and *p*-hydroxybenzoic acid, sodium H-malate, sodium pyruvate, and sodium succinate (0.1% w/v) are used as sole carbon sources, but not adonitol, inulin, salicin, sucrose (1.0%, w/v), benzoate, or butyrate (0.1%, w/v). Acetamide, gelatin, and L-glutamate are used as sole carbon and nitrogen sources, but not L-alanine, L-aspartic acid, L-leucine, monooleic ethanolamine, L-proline, L-phenylalanine, urea, uric acid, or L-valine (all at 0.1%, w/v).

Grows in the presence of oleic acid (0.1%, w/v) and zinc chloride (0.001%, w/v).

Mycolic acids have 54–62 carbon atoms with C_{58} and C_{60} as the main components. The predominant menaquinone is MK-9(H_2).

Source: Kalahari sand collected in the Walerberg area of central Namibia.

DNA G+C content (mol%): not determined.

Type strain: NAM-BN063A, DSM 44568, NCIMB 13780.

Sequence accession no. (16S rRNA gene): AF380930.

Sequence accession no. (gyrB): gy12629.

15. **Gordonia otitidis** Iida, Taniguchi, Kageyama, Yazawa, Chibana, Murata, Nomura, Kroppenstedt and Mikami 2005, 1874[VP]

o.ti′ti.dis. Gr. n. *ous otos* ear; L. suff. *itis*, *idis* suffix used in names of inflammations; N.L. gen. n. *otitidis* of inflammation of the ear.

Partially acid-fast, short elementary branching hyphae fragment into rod- and coccoid-like elements (0.6–0.8 × 2.5–3.1 μm). Colonies are white becoming apricot to pale orange.

Utilizes acetamide, *N*-acetyl-D-glucosamine, L-alanine, 4-aminobutyrate, benzoate, 4-hydroxybenzoate, 2-hydroxyvalerate, 2-oxoglutarate, phenylacetate, L-proline, putrescine, quinate, L-serine, and L-valine, but not L-aspartate, caprate, citrate, galactose, glucarate, gluconate, 3-hydroxybenzoate, *meso*-inositol, rhamnose, ribose, succinate, or tyramine.

Mycolic acids have 58–64 carbon atoms with C_{62} as the main component. The major fatty acids are $C_{16:0}$ (31.7%), 16:1 *cis*9 (18.9%), $C_{18:11}$ (18.2%), and 10-methyl $C_{18:0}$ (23.0%). The predominant menaquinone is MK-9(H_2); a substantial amount of MK-8(H_2) is also produced.

Source: ear discharge of a patient with external otitis, and from pleural fluid of a patient with bronchitis.

DNA G+C content (mol%): 64.9–65.2 (HPLC).

Type strain: IFM 10032, CCUG 52243, DSM 44809, JCM 12355, NBRC 100426.

Sequence accession no. (16S rRNA gene): AB122026.

16. **Gordonia paraffinivorans** Xue, Sun, Zhou, Liu, Liang and Ma 2003, 1645[VP]

pa.raf.fi.ni.vo′rans. N. L. n. *paraffina* paraffin; L. part. adj. *vorans* devouring; N. L. part. adj. *paraffinivorans* paraffin-devouring, referring to the ability to degrade paraffin.

Non-acid-fast rod-shaped actinomycete (0.3–0.5 × 1–2 μm). Cells occur singly or in typical coryneform V-shapes. Colonies orange-red. Grows well at 30–37°C, but slowly at 20° and 45°C. Grows at pH 5.5–9.5.

Catalase-positive, oxidase-negative. Does not degrade arbutin, gelatin, cellulose, or Tween 20.

Does not produce acid from galactose, glucose, glycerol, mannose, or sucrose. L-Alanine, dextrin, fructose, galactose, glucose, glutamate, glycerol, L-leucine, maltose, L-proline, and sucrose are used as sole carbon sources, but not L-arabinose, arabitol, citrate, esculin, lactate, L-lysine, L-malic acid, mannitol, raffinose, rhamnose, ribose, L-sorbose, sorbitol, tartrate, or xylose.

Grows in the presence of oleic acid (0.8%, w/v) and zinc chloride (0.001%, w/v).

Mycolic acids have 52–62 carbon atoms. The major fatty acids are $C_{16:0}$ (25.8%), $C_{18:1}$ ω9*c*, $C_{18:0}$ (9.3%), and 10-methyl $C_{18:0}$ (22.4%). The predominant menaquinone is MK-9(H_2).

Source: a producing-well water sample from Daqing oilfield, China.

DNA G+C content (mol%): 66 (T_m).

Type strain: HD 321, AS 4.1730, DSM 44604, JCM 12461.

Sequence accession no. (16S rRNA gene): AF432348.

17. **Gordonia polyisoprenivorans** Linos, Steinbücher, Spröer and Kroppenstedt 1999, 1789[VP]

po.ly.i.so.pre.ni.vo′rans. N.L. n. *polyisoprenum* polyisoprene; L. part. adj. *vorans* devouring; N.L. part. adj. *polyisoprenivorans* polyisoprene eating, referring to the ability to degrade polyisoprene.

Slightly acid-fast, elementary branching hyphae fragment into rod- and coccoid-like elements. Smooth creamy beige colonies become pastel orange when cultivated in the presence of light.

Does not hydrolyze 2-desoxythymidine-5-*p*-nitrophenyl phosphate, *p*-nitrophenylphosphoryl choline, or *p*-nitrophenyl-β-D-xyloside.

Utilizes acetamide, L-alanine, D-arabitol, L-aspartate, benzoate, 4-hydroxybenzoate, citrate, galactose, gluconate, D-glucosaminic acid, *meso*-inositol, L-proline, putrescine, quinate, rhamnose, sucrose, turanose, and valine by means of the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) reduction test, but not 4-aminobenzoate,

caprate, D-glucarate, 3-hydroxybenzoate, 2-hydroxyvalerate, L-leucine, 2-oxoglutarate, phenylacetate, pimelate, ribose, L-serine, or succinate.

Mycolic acids have 58–64 carbon atoms with C_{60} and C_{62} as the main components. The major fatty acids are $C_{16:1}$ (12%), $C_{16:0}$ (29%), $C_{18:1}$ (21%), and 10-methyl $C_{18:0}$ (29%). The predominant menaquinone is MK-9(H_2). The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: fouling tire water inside a deteriorated automobile tire in Munster, Germany.

DNA G+C content (mol%): not determined.

Type strain: Kd 2, ATCC BAA-14, CIP 106350, DSM 44302, JCM 10675, NBRC 16320.

Sequence accession no. (16S rRNA gene): Y18310.

Sequence accession no. (gyrB): ABO75556.

18. **Gordonia rhizosphera** Takeuchi and Hatano 1998, 910[VP]

rhi.zo.sphe′ra. Gr. fem. n. *rhiza* root; Gr. fem. n. *sphaira* ball, sphere; L. (*sic*) fem. adj. (*sic*) *rhizosphera* (*sic*) within the sphere of the root (*sic*).

Rod-shaped actinomycete (0.2–0.4 × 0.4–1.0 μm) which forms pink to orange colonies with irregular margins and flat, rough surfaces on standard media, including HV and PY agars.

Catalase-positive and oxidase-negative.

Acid is produced from rhamnose (weakly), but not from galactose, *meso*-inositol, sorbitol, sucrose, or trehalose. Grows on L-alanine, citrate, gluconate, L-leucine (weak), L-proline (weak), and L-valine (weak) as sole carbon sources, but not on acetamide, aspartate, benzoate, galactose, *meso*-inositol, ribose, succinate, or sucrose.

Mycolic acids have 56–64 carbon atoms with C_{60} and C_{62} as the main components. The major fatty acids are $C_{16:0}$ (27%), $C_{17:0}$ (13%), $C_{18:1}$ 10-methyl $C_{18:0}$ (27%); only traces of tuberculostearic acid are present. The predominant menaquinone is MK-9(H_2).

Source: rhizophere of *Bruguiera gymnorrhiza* Lank, in the Shiira River estuary, Iriomote Island, Japan.

DNA G+C content (mol%): 66.8 (HPLC).

Type strain: 141, DSM 44383, IFO 16068, NBRC 16068.

Sequence accession no. (16S rRNA gene): AB004729.

Sequence accession no. (gyrB): ABO75552.

19. **Gordonia rubripertincta** corrig. (Hefferan 1904) Stackebrandt, Smida and Collins 1989[VP] (Effective publication: Stackebrandt, Smida and Collins 1988; basonym: *Rhodococcus rubropertinctus* (Hefferan 1904) Tsukamura 1974; *Rhodococcus corallinus* (Bergey, Harrison, Breed, Hammer and Huntoon 1923) Goodfellow and Alderson 1977, 115)

ru.bri.per.tinc′ta. L. adj. *ruber -bra -brum* red; L. pref. *per* very; L. fem. part. adj. *tincta* dyed, colored; N.L. fem. part. adj. *rubripertincta* heavily dyed red.

Rod–coccus life cycle. Rough, orange to red colonies formed on egg media, glucose-yeast extract agar and Sauton's agar. Grows at 25°C and 40°C, but not at 10°C or 45°C.

Positive for allantoinase, β-esterase, and urease, but negative for acetamidase, acid phosphatase, benzamidase, α-esterase, β-galacturonidase, isonicotinamidase, malonamidase, nicotinamidase, pyrazinamidase, salicylamidase, and succinamidase.

Acid is produced from glucose, mannitol, mannose, and sorbitol, but not from arabinose, galactose, inositol, raffinose, rhamnose, or xylose. Butan-2,3-diol, 2,3 butylene glycol, butane 2,3-diol, *p*-cresol, ethanol, glycerol, *m*-hydroxybenzoic acid, inulin, mannitol, propan-1-ol, sodium citrate, sodium gluconate, sodium malate, sodium octanoate, sodium succinate, sucrose, trehalose, and testosterone are used as sole carbon sources, but not acetamide, L-glutamate, *p*-hydroxybenzoic acid, inositol, propane -1,2-diol, propylene glycol, rhamnose, salicin, sorbitol, sodium benzoate, sodium malate, sodium lactate, sodium malonate, sodium pimelate, sodium pyruvate, sodium sebacate, or L-tyrosine. Glucosamine hydrochloride and monoethanolamine are used as sole carbon and nitrogen sources, but not acetamide, D-alanine, L-alanine, L-asparagine, benzamide, serine, L-threonine, or trimethylenediamine.

Resistant to crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), picric acid (0.2%, w/v), sodium azide (0.01%, w/v), sodium-*p*-aminosalicylic acid (0.2%, w/v), sodium chloride (7%, w/v), and sodium nitrite (0.1%, w/v). Resistant to (μg per ml) chlortetracycline (4), ethambutol (5), gentamicin (16), neomycin (4), and penicillin G (32), but is sensitive to fluorouracil (20), mitomycin C (5), rifampin (25), and vancomycin (2).

Mycolic acids have 48–62 carbon atoms. The major fatty acids are $C_{16:1}$ ω9*c* (15%), $C_{16:0}$ (37%), $C_{18:1}$ (19%), and 10-methyl $C_{18:0}$ (19%). The predominant menaquinone is MK-9(H_2).

Source: soil.

DNA G+C content (mol%): 67–69 (T_m).

Type strain: strain N4, ATCC 14352, CCUG 34957, CIP 104661, DSM 43197, JCM 3204, LMG 5367, KCC A-0204, NCIMB 9664, NBRC 101908, VKM Ac-1016.

Sequence accession no. (16S rRNA gene): X80632.

Sequence accession no. (23S rRNA gene): AY956799.

Sequence accession no. (gyrB): AY972061.

20. **Gordonia shandongensis** Luo, Gu, Xie, Hu, Liu and Huang 2007, 607[VP]

shan.dong.en′sis. N.L. fem. adj. *shandongensis* of or belonging to Shandong Province, China, the source of the type strain.

Slightly acid-fast actinomycete which forms a short elementary mycelium that fragments into rod- and coccoid-like elements. Rough, light yellow colonies are formed on yeast extract-malt extract agar. Grows well at 20–37°C, and from pH 5.0–9.0.

Hydrolyzes urea. Degrades guanine, but not casein.

D-Arabinose and cellobiose are used as sole carbon sources, but not L-alanine, L-arginine, L-aspartate, L-hydroxyproline, L-proline, rhamnose, ribose, sodium benzoate, sodium citrate, sodium sebacate, sodium succinate, or L-valine.

Mycolic acids have been detected by one-dimensional thin-layer-chromatography. The major fatty acids are $C_{15:0}$ iso 2-OH (14.6%), $C_{16:0}$ (36%), $C_{18:1}$, $C_{18:1}$ω9*c* (21%), 10-methyl $C_{18:0}$ (15%), and $C_{15:0}$ iso 2-OH (15%). The predominant menaquinone is MK-9(H_2). The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: farmyard soil in Shangdon Province, China.

DNA G+C content (mol%): not determined.

Type strain: SD29, CGMCC 4.3492, DSM 45094, JCM 13907.

Sequence accession no. (16S rRNA gene): DQ420167.

21. **Gordonia sihwensis** Kim, Lee, Kroppenstedt, Stackebrandt and Lee 2003, 1432^VP

sih.wen′sis. N.L. fem. adj. *sihwensis* of or belonging to Lake Sihwensis in Korea, the source of the type strain.

Non-acid-fast, branching hyphae fragment into rod- and coccoid-like elements. Rough, white to tan colonies with irregular margins are formed on standard nutrient media.

Hydrolyzes 2-deoxythymidine-5-*p*-nitrophenyl phosphate, *p*-nitrophenyl-phosphorylcholine, but not *p*-nitrophenyl-β-D-xyloside.

N-Acetyl-D-glucosamine, 4-aminobutyrate, D-arabitol, caprate, citrate, galactose, gluconate, D-glucosaminic acid, 2-hydroxyvalerate, L-leucine, 2- oxoglutarate, phenylacetate, pimelate, L-proline, L-serine, sucrose, turanose, and L-valine are used as sole carbon sources, but not acetamide, L-aspartate, benzoate, glutarate, 3- and 4-hydroxybenzoate, putrescine, quinate, rhamnose, ribose, succinate, or tyramine.

Mycolic acids have 48–56 carbon atoms with C_{52}, C_{53}, C_{54}, and C_{56} as the main components. The major fatty acids are $C_{16:1}$ *cis*9 (19%), $C_{16:0}$ (39%), $C_{18:1}$ (12%), and $C_{18:0}$ 10-methyl (22%). The predominant menaquinone is MK-9(H_2), a small amount of MK-8(H_2) is also produced. The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: a sulfur-oxidizing autotrophic denitrification reactor used for advanced treatment of wastewater from Lake Sihwa, Korea.

DNA G+C content (mol%): not determined.

Type strain: SPR2, DSM 44576, JCM 13435, NRRL B-24155.

Sequence accession no. (16S rRNA gene): AJ416151.

22. **Gordonia sinesedis** Maldonado, Stainsby, Ward and Goodfellow 2003, 79^VP

sine.se′dis. L. prep. *sine* without; L. n. *sedes -is* dwelling place, residence, habitation; N.L. gen. (?) n. (?) *sinesedis* of homeless (?), intended to mean without home, reflecting the unstable position of the organism in the *Gordonia* 16S DNA tree.

Slightly acid–alcohol-fast actinomycete which forms long thin rods and coccoid elements. Dry, creamish colonies are formed on glucose-yeast extract agar. Grows well at 20–40°C, and pH 4.5–9.5.

Acetate, D-arabinose, *iso*-butanol (weak), cellobiose, dulcitol, *meso*-erythritol (weak), ethanol, fructose, D-fucose, fumarate, galactose, gluconate, glycerol (weak), glycogen, glucose, *m*- and *p*-hydroxybenzoic acid, *meso*-inositol, lactose, H-malate, mannose, melezitose, melibiose, α-methyl-D-glucoside, *iso*-propanol, pyruvate, raffinose, ribose, succinate, trehalose, xylitol, and xylose are used as sole carbon sources, but not L-alanine, L-aspartic acid, L-leucine, monoethanolamine, L-phenylalanine, L-proline, urea, uric acid, or L-valine.

Grows in the presence of oleic acid (0.1%, w/v) and zinc chloride (0.001% w/v).

Mycolic acids have 58–62 carbon atoms as the main components. The major fatty acids are $C_{17:0}$ (7.3%), $C_{16:0}$ (19.9%), $C_{16:0}$ *cis*7 (9.5%), $C_{18:0}$ (8.8%), and 10-methyl $C_{18:0}$ (11.7%). The predominant menaquinone is MK-9(H_2), but MK-8(H_2) is also produced.

Source: soil adjacent to the river Thames.

DNA G+C content (mol%): not determined.

Type strain: J72, DSM 44455, JCM 121126, NCIMB 13802.

Sequence accession no. (16S rRNA gene): AF380834.

23. **Gordonia soli** Shen, Goodfellow, Jones, Chen, Arun, Lai, Rekha and Young 2006a, 2599^VP

so′li. L. gen. n. *soli* of/from the soil.

Partially acid–alcohol-fast actinomycete which forms elementary branching hyphae that fragment into rods and cocci. Pale orange, circular colonies (about 2 mm in diameter) with filamentous margins are formed on tryptic soy agar after 2 d at 30°C. Grows at 28–35°C, but not at 4° or 40°C. Grows at pH 5.5–10.0.

Positive for acid and alkaline phosphatase, butyrate esterase, caprylate esterase, α- and β-glucosidase, naphthol-AS-BI phosphohydrolase, pyrazinamidase, and urease, but negative for *N*-acetyl-β-glucosamidase, α-chymotrypsin, α-fucosidase, α- or β-galactosidase, β-glucuronidase, leucine arylamidase, α-mannosidase, pyrrolidonylarylamidase, and trypsin.

N-Acetyl-L-glutamic acid, D-alanine (weak), L-alanine, L-alanyl glycine (weak), L-alaninamide, α-and β-cyclodextrin, D-fructose-6-phosphate (weak), α-D-glucose, L-glutamic acid, glycogen (weak), α-and β-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, DL-lactic acid (weak), D-malic acid (weak), mannan, mannose, 3-methyl-D-glucose (weak), D-psicose, L-pyroglutamic acid, pyruvic acid (weak), putrescine, sorbitol (weak), succinate (weak), sucrose (weak), Tweens 20 and 40, and uridine 5-monophosphate are used as sole carbon sources.

Mycolic acids co-migrate with those extracted from the type strain of *Gordonia bronchialis*. The major fatty acids are $C_{16:0}$ (33.6%), $C_{16:1}$ (10.4%), $C_{18:1}$ (11.7%), and $C_{18:0}$ 10-methyl (29.4%). The predominant menaquinone is MK-9(H_2). The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: the campus of the National Chung Hsing University, Taiching, Taiwan.

DNA G+C content (mol%): not determined.

Type strain: CC-AB07, BCRC 16810, DSM 44995.

Sequence accession no. (16S rRNA gene): AY995560

Sequence accession no. (gyrB): gy10475.

24. **Gordonia sputi** (Tsukamura 1978) Stackebrandt, Smida and Collins 1989^VP emend. Riegel, Kamne-Fotso, De Briel, Prévost, Jehl, Piédmont and Monteil 1994, 766^VP (*Rhodococcus sputi* Tsukamura 1978, 181; *Gordonia sputi* Stackebrandt, Smida and Collins 1988, 371; basonym: *Rhodococcus sputi* Tsukamura and Yamo 1985, 365; *Rhodococcus chubuensis* Tsukamura 1982a, 1116)

spu′ti. L. gen. n. *sputi* of discharge from the respiratory tract.

Slightly acid-fast short rods and cocci. Rough pink colonies formed on egg media and Sauton's agar. Dry, raised, beige colonies that become salmon colored after several days growth on Mueller–Hinton medium. Grows at 28°C and 37°C, but not at 42°C.

Positive for acetamidase, acid phosphatase, α-and β-esterase, nicotinamidase, pyrazinamidase, and urease, but negative for benzamidase, β-galactosidase, isonicotinamidase, salicylamidase, and succinamidase.

Acid is formed from glucose, mannitol, mannose, sorbitol, and trehalose, but not from arabinose, galactose, *meso*-inositol, rhamnose, or xylose. Grows on acetate, *n*-butanol, citrate, ethanol, fructose, glucose, L-malate, mannitol, mannose, *n*-propanol, pyruvate, sorbitol, sucrose, succinate, and trehalose as sole carbon sources, but not on benzoate, 1,3- or 1, 4 – butylene glycol, *meso*-inositol, malonate, propylene glycol, or rhamnose. Acetamide, nicotinamide, nitrate, and succinamide are used as sole nitrogen sources, but not benzamide, isonicotinamide, or nitrate. Acetamide and monoethanolamine are used as sole carbon and nitrogen sources, but not D-alanine, L-alanine, L-asparagine, glucosamine, L-serine, or L-threonine.

Grows in the presence of *p*-nitrobenzoic acid (0.5 mg) and picric acid (0.2%, w/v), but not in the presence of sodium nitrite (0.1%, w/v) or sodium salicylate (0.1%, w/v). Resistant to (μg per ml) chlortetracycline (4), ethambutol (5), neomycin (4), oleandomycin (32), rifampin (25), and vancomycin (4), but sensitive to 5-fluorouracil (20), gentamicin (16), mitomycin C (5), penicillin G (32), and rifampin (8).

Mycolic acids have 56–66 carbon atoms with 2–6 double bonds. The major fatty acids are $C_{16:0}$ (44%), $C_{18:1}$ (29%), and $C_{18:0}$ 10-methyl (15%). The predominant menaquinone is MK-9(H_2); significant amounts of MK-8(H_2) are also produced.

DNA G+C content (mol%): 65.2 (HPLC).

Type strain: ATCC 29627, CCUG 47138, CIP, 100849, DSM 43896, IMET 7569, JCM 3228, KCC A-0228, NBRC 16049, NBRC 100414.

Sequence accession no. (16S rRNA gene): X80634.

Sequencek accession no. (gyr B): AY972064.

25. **Gordonia terrae** (Tsukamura 1971) Stackebrandt, Smida and Collins 1989, 371[VP] [*Gordonia terrae* Tsukamura 1971, 22; basonym *Rhodococcus terrae* (Tsukamura 1971) Tsukamura 1974, 43[VP]; *Gordonia terrae* Stackebrandt, Smida and Collins 1989, 371[VP]]

ter′ra.e. L.n. *terra* earth, L. gen. n. *terrae* of the earth.

Rod–coccus life cycle. Rough, pink to orange colonies are formed on egg media, Sauton's agar, and yeast extract agar.

Positive for allantoinase, β-esterase, α-esterase, nicotinamidase, pyrazinamidase, and urease, but negative for acetamidase, acid phosphatase, benzamidase, β-galactosidase, isonicotinamidase, malonamidase, and salicylamidase.

Acid is produced from mannitol, rhamnose, sorbitol, and trehalose, but not from arabinose, galactose, inositol, *p*-cresol, or xylose. Grows on ethanol, glycerol, *p*-hydroxybenzoic acid, inulin, maltose, mannitol, propanol, rhamnose, sorbitol, sodium azide, sodium citrate, sodium lactate, sodium malate, sodium octanoate, sodium pimelate, sodium pyruvate, sodium sebacate, sodium succinate, sucrose, testosterone, trehalose, L-tyrosine as sole carbon sources, but not on acetamide, butan-2,3-diol, 1,3-, -1,4-, or 2,3-butylene glycol, inositol, *m*-hydroxybenzoic acid, propane-1, 2-diol, or sodium malonate. Acetamide, L-alanine, benzamide, isonicotinamide, nicotinamide, nitrate pyrazinamide, and urea are used as sole nitrogen sources, but not D-alanine, or nitrate. L-Glutamate and monoethanolamine are used as sole sources of carbon and nitrogen, but not acetamide, benzamide, L-serine, or trimethylenediamine.

Resistant to picric acid (0.2%, w/v), sodium *p*-aminosalicylate (0.2%, w/v), and sodium nitrate (0.1%, w/v), but is sensitive to sodium salicylate (0.1 % w/v). Resistant to (μg per ml) chlorotetracycline (4), ethambutol (5), gentamicin (16), neomycin (4), oleandomycin (32), penicillin G (32), rifampin (25), and vancomycin (4), but sensitive to 5-fluorouracil (40) and mitomycin C (5).

Mycolic acids have 52–64 carbon atoms. The major fatty acids are $C_{16:1}$ *cis*9 (16%), $C_{16:0}$ (32%), $C_{18:1}$ (26%), and methyl-$C_{18:0}$ (17%). The predominant menaquinone is MK-9(H_2).

Sequence accession no. (16S rRNA gene): X79286.

Sequence accession no. (gyrB): gy10475.

26. **Gordonia westfalica** Linos, Berekara, Steinbüchel, Kim, Spröer and Kroppenstedt 2002, 1137[VP]

west.fa′li. ca. N.L. fem. adj. *westfalica* of or belonging to Westfalia, referring to the origin of the species from a geographical area in Germany.

Slightly acid-fast, short, elementary branching hyphae fragment into rod- and coccoid-like elements. Smooth and rough, pastel orange colonies formed on nutrient agar.

Degrades and mineralizes natural rubber substrates and synthetic *cis*-1,4-polyisoprene.

Utilizes L-aspartate, benzoate, caprate, citrate, D-glucosaminic acid, 2-oxoglutarate, ribose, and sucrose by means of the MTT reduction test, but not acetamide, *N*-acetyl-D-glucosamine, L-alanine, 4-aminobutyrate, galactose, glucarate, gluconate, 3- and 4-hydroxybenzoate, 2-hydroxyvalerate, inositol, L-leucine, pimelate, phenylacetate, putrescine, L-proline, quinate, rhamnose, turanose, L-serine, succinate, tyramine, or L-valine.

Mycolic acids have 54–62 carbon atoms with C_{56}, C_{58}, and C_{60} as main components. The major fatty acids are $C_{16:1}$ *cis*9 (12%), $C_{16:0}$ (37%), $C_{18:1}$ (29%), and methyl $C_{18:0}$ (13%). The predominant menaquinone is MK-9(H_2). The cellular polar lipid composition includes diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides.

Source: foul water from inside a deteriorated automobile tire found in a field near Munster, Westfalia, Germany.

DNA G+C content (mol%): not determined.

Type strain: Kb2, CCUG 46924, DSM 44215, JCM 11757, NRRL B-24152.

Sequence accession no. (16S rRNA gene): AJ312907.

Sequence accession no. (gyrB): gy12627.

Species *incertae sedis*

1a. **"Gordonia jacobaea"** de Miguel, Sieiro, Poza and Villa 2000, 108

Gram-stain-positive, non-sporing, rod-shaped cells with a tendency to bipolar staining. Grows at 25°C and 35°C. Metabolizes methyl pyruvate and Tweens 20 and 40, but gives negative or variable results for the other tests in the Biolog System. A rich source of carotenoids, including the ketocarotenoid *trans*-canthaxanthine.

Source: air.

DNA G+C content (mol%): 61 (thermal hyperchromisity method).

Sequence accession no. (16S rRNA gene): AF251791.

Additional remarks: this is probably a good species but it has not been validly published. "*Gordonia jacobaea*" MV-1 is most closely related to the type strain of *Gordonia sputi*; the two strains share a 16S rRNA gene sequence of 99.5%.

Genus III. **Millisia** Soddell, Stainsby, Eales, Kroppenstedt, Seviour and Goodfellow 2006a, 742[VP]

Jacques A. Soddell, Simon J. McIlroy and Robert J. Seviour

Mil.li′si.a N.L. fem. n. named after Nancy F. Millis, a celebrated microbiologist who promoted wastewater microbiology in Australia

Aerobic, Gram-stain-positive to Gram-stain-variable, acid–alcohol-fast, nonmotile, catalase-positive actinomycete that **forms non-sporing rods which show only rudimentary right-angled branching and which contain polyphosphate storage granules. In stationary phase, the rods fragment into spherical unicells** (Figure 94). Salmon pink, irregular colonies with filamentous margins and sparse unbranched aerial hyphae are formed on glucose-yeast extract agar. Colonies are matt and dry in appearance, soft in texture, and easy to emulsify. Diffusible pigments are not produced. **Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid, arabinose, and galactose.** The organism contains *N*-glycolated muramic acid residues, **a predominant dihydrogenated menaquinone with eight isoprene units, and diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides as major polar lipids. Mycolic acids have 44–52 carbon atoms (principal components C_{48}, C_{50}, and C_{52}), and oleic, palmitic, and palmitoleic acids are the predominant fatty acids, with relatively small amounts of myristic, stearic, and tuberculostearic acids.** A member of the family *Nocardiaceae* in the order *Corynebacteriales*.

Isolated from activated sludge foam from Tamworth Sewage Treatment Plant, New South Wales, Australia.

DNA G+C content (mol%): 64.7 (HPLC).

Type species: **Millisia brevis** Soddell, Stainsby, Eales, Kroppenstedt, Seviour and Goodfellow 2006a, 742[VP].

Further descriptive information

The genus description is based on two isolates (J81[T] and J82) from a single source. Comparison of the 16S rRNA gene sequences of these strains show that they form a deep-rooted lineage in the *Corynebacteriales* tree (Figure 95) that is most closely related to *Gordonia* species (93.7–95.7% similarity) and *Skermania piniformis* (95.5% similarity) (Soddell et al., 2006a). The decision to place these isolates with a distinctive branched filament morphology (Figure 94) into a separate and novel genus was based on their phenotypic (Soddell and Seviour, 1998) and genotypic properties, and their menaquinone, polar lipid, cell wall, and mycolic acid compositions (Soddell et al., 2006a). High levels of oleic acid ($C_{18:1}$; 26.3%) and low levels of tuberculostearic acid (3%) distinguish them from members of other mycolic acid containing genera. Thin layer chromatography analysis of mycolic acids showed these were similar in their

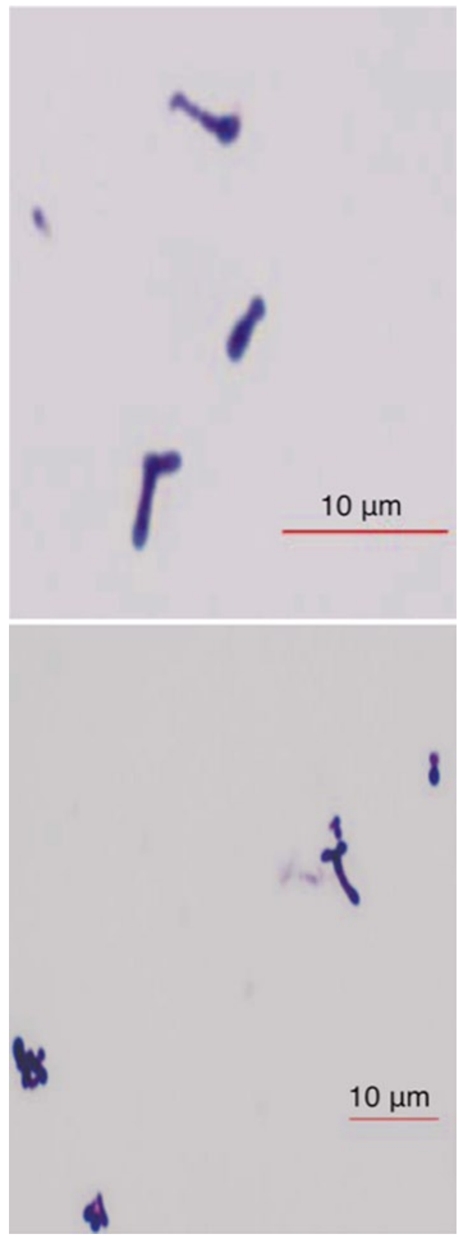

FIGURE 94. Micrographs showing distinctive rudimentary branching filamentous morphology of *Millisia brevis*, and the presence of unicellular elements thought to arise from filament fragmentation.

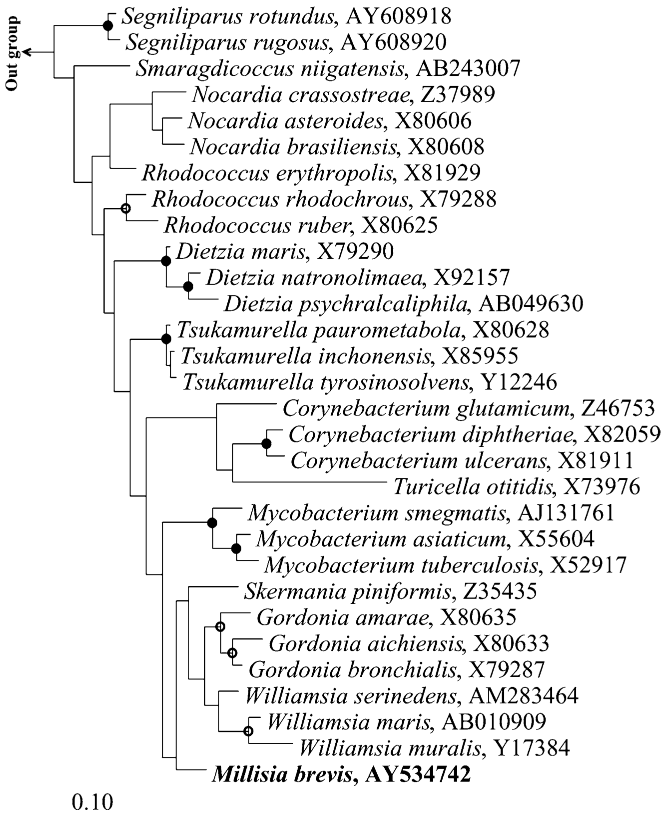

FIGURE 95. Maximum-likelihood tree (Felsenstein, 1981) constructed using ARB software, based on almost complete 16S rRNA gene sequences of *Millisia brevis* and selected type strain of species that are representative of genera classified in the order *Corynebacteriales*. Parsimony bootstrap values were calculated as a percentage of 1000 trials and are only indicated for values ≥75%. ○ Indicates a bootstrap value of ≥75% and ● indicates a bootstrap value of 95%. The sequence of *Bacillus thuringiensis* (X55062) was used to root the tree. The scale bar represents the number of substitutions per nucleotide position.

chromatographic behavior to those in representative *Gordonia* and *Rhodococcus* strains. However, Curie-point pyrolysis mass spectrometry (PyMS) analysis of strain J81^T clearly separated it from representatives of all other currently described mycolic acid containing genera (Soddell et al., 2006a). An organism (isolate J855) with an identical partial 16S rRNA gene sequence has been cultured from a marine invertebrate in Puerto Rico (Sfanos et al., 2005).

Enrichment and isolation procedures

Millisia was obtained by micromanipulation of rudimentary branched filaments with a Skerman micromanipulator onto standard methods agar (BBL SMAS medium, Becton-Dickinson) supplemented with 1% (v/v) horse serum from surface foam in an aerated reactor at a wastewater treatment plant in Tamworth, NSW, Australia (Soddell and Seviour, 1994). After incubation at 25°C, two strains (J81^T and J82) were obtained in pure culture. Both were shown to be members of the same species (Soddell and Seviour, 1998; Soddell et al., 2006a). They were preserved at −80°C.

Taxonomic comments

The two *Millisia* strains have 16S rRNA signature nucleotides that are characteristic of members of the order *Corynebacteriales*, but not characteristic of their closest phylogenetic neighbors in the family *Gordoniaceae* (Stackebrandt et al., 1997). The family *Gordoniaceae* is not used in the present volume, and the phylogenetic analysis used for the roadmap places *Millisia* within the family *Nocardiaceae* (Zhi et al., 2009; Ludwig et al., 2012 – the roadmap to this volume).

List of species of the genus *Millisia*

1. **Millisia brevis** Soddell, Stainsby, Eales, Kroppenstedt, Seviour and Goodfellow 2006a, 742^{VP}

bre′vis. L. fem. adj. short, denoting the formation of short branched rods.

In addition to the properties given under the genus description, the organism degrades Tweens 20, 40, and 60, but not adenine, casein, elastin, hypoxanthine, tyrosine, or xanthine. Hydrolyzes allantoin (weak) and urea (strong), but does not reduce nitrate or produce *m*- or *p*-nitrophenol oxidases. Grows between 15°C and 35°C, but not at 10°C or 37°C, and from pH 5.5 to 9.5. Cellobiose, ethanol, fructose, glucose, glycerol, inositol, mannitol, mannose, sucrose, and trehalose are used as sole sources of carbon for energy and growth, but not arabinose, galactose, inulin, lactose, maltose, melezitose, raffinose, rhamnose, salicin, sorbitol, or xylose (all at 0.1%, w/v). Similarly, *m*-hydroxybenzoic acid, sebacic acid, sodium butyrate, sodium gluconate, sodium lactate, sodium octanoate, and sodium pyruvate are used as sole carbon sources, but not acetamide, benzamide, *p*-hydroxybenzoic acid, pimelic acid, sodium benzoate, sodium succinate, sodium tartrate, testosterone, or tyrosine (0.01%, w/v); variable results are obtained with *p*-cresol, sodium acetate, sodium adipate, sodium citrate, sodium fumarate, sodium malate, and sodium propionate (all at 0.1%, w/v). Coconut oil, glycerol trioleate, kerosene, hexadexane, olive oil, paraffin oil, safflower oil, and xylene (weak) are used as sole carbon sources in shake flask liquid culture (all at 1%, v/v). Variable results were obtained with acetamide and serine as sole carbon and nitrogen sources, but trimethyldiamine does not support growth. Grows in the presence of crystal violet (0.0001%, w/v), phenol (0.01%, w/v), and phenyl ethanol (0.02 and 0.03%, v/v), but is sensitive to crystal violet (0.001%, w/v), phenol (0.1%, w/v), sodium azide (0.01 and 0.02%, w/v), sodium chloride (5 and 7%, w/v), and penicillin G (10 international units). Produces acid

phosphatase, alkaline phosphatase (weak), esterase (C_4), esterase lipase (C_8), α-and β-glucosidases, leucine arylamidase, α-mannosidase (weak), naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but not chymotrypsin, lipase (C_{14}), α-fucosidase, α- and β-galactosidases, β-glucuronidase, *N*-acetyl-β-glucosaminidase, or trypsin; variable for cystine arylamidase.

DNA G+C content (mol%): 64.7 (HPLC).

Type strain: J81, DSM 44463, JCM 13999, NRRL B-24424.

Sequence accession no. (16S rRNA gene): AY534742.

Genus IV. **Rhodococcus** (Zopf 1891) emend. Goodfellow, Alderson and Chun 1998a

Amanda L. Jones and Michael Goodfellow

Rho.do.coc′cus. Gr. n. *rhodon* the rose; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Rhodococcus* a red coccus.

Aerobic, Gram-stain-positive to Gram-stain-variable, nonmotile actinomycetes **that are usually partially acid–alcohol-fast at some stage of the growth cycle. Rods to extensively branched substrate mycelium may be formed.** In all strains the growth cycle begins with the coccus or short rod stage, with different organisms showing a succession of more or less complex morphological stages by which the completion of the cycle is achieved. Cocci may germinate into short rods, form filaments with side projections, show elementary branching, or, in the most differentiated forms, produce extensively branched hyphae. The next generation of cocci and short rods are formed by fragmentation of the rods, filaments, and hyphae. Some strains form sparse microscopically visible aerial hyphae, which may be branched, or aerial synnemata consisting of unbranched filaments that coalesce and project upwards. Colonies may be rough, smooth, or mucoid and pigmented buff, cream, orange, red, or yellow, although colorless variants occur. Chemo-organotrophic with an oxidative type of metabolism. Catalase-positive, arylsulfatase-negative, and sensitive to lysozyme. Most strains grow well on standard media between 15 and 40°C, and use a wide range of organic compounds as sole sources of carbon for energy and growth.

Whole-organism hydrolysates are rich in *meso*-2,6-diaminopimelic acid, arabinose, and galactose. The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-glycolated. **Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids, and major proportions of straight-chain saturated, monounsaturated, and branched-chain fatty acids (e.g., 10-methyloctadecanoic acid), and dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue. Mycolic acids have 30–54 carbon atoms and up to 4 double bonds. The fatty acids released on pyrolysis gas chromatography of mycolic acid esters have 12–16 carbon atoms.** The genus *Rhodococcus*, as determined by 16S rRNA gene sequence analysis, is classified in the order *Corynebacteriales.*

Rhodococci are widely distributed in aquatic and terrestrial habitats, notably in herbivorous dung, soil and marine sediments. Some are opportunistic pathogens of animals, including humans, others are plant pathogens.

DNA G+C content (mol%): 63–73 (HPLC, T_m).

Type species: **Rhodococcus rhodochrous** (Zopf 1889) Tsukamura 1974, 43[VP].

Further descriptive information

Phylogeny. The genus *Rhodococcus* is a member of the family *Nocardiaceae* which also encompasses the genera *Nocardia* Trevisan 1889 and *Smaragdicoccus* Adachi et al., (2007). These taxa form a distinct phyletic branch in the *Corynebacteriales* 16S rRNA gene tree (Figure 96). Rhodococci are classified into 30 validly published species which can be assigned to three taxa in the *Rhodococcus* 16S rRNA gene tree, namely the *Rhodococcus equi, Rhodococcus erythropolis,* and *Rhodococcus rhodochrous* subclades; the taxonomic integrity of the latter are supported by relatively high bootstrap values (Figure 96). The position of *Rhodococcus equi* within the evolutionary radiation encompassed by the genera *Nocardia* and *Rhodococcus* is not stable. It is not clear whether *Rhodococcus equi* is more closely related to the genus *Nocardia* than to other members of the genus *Rhodococcus* or whether it should be recognized as a genus in its own right (Goodfellow et al., 1998a; McMinn et al., 2000; Rainey et al., 1995a; Ruimy et al., 1994).

Cell morphology. Rhodococci have no distinctive morphological features other than the ability of most strains to form hyphae that fragment into rods and cocci, but they do show considerable heterogeneity (Goodfellow et al., 2004; Helmke and Weyland, 1984; Locci, 1976, 1981; Locci and Sharples, 1984; Mayilraj et al., 2006; Nesterenko et al., 1982; Williams et al., 1976). *Rhodococcus aetherivorans* and *Rhodococcus kroppenstedtii* have been reported to be amycelial, but further morphological development is represented by *Rhodococcus erythropolis, Rhodococcus globerulus,* and *Rhodococcus rhodochrous,* as they show elementary branching prior to fragmentation. *Rhodococcus equi* shows traces of elementary branching at early stages of growth. *Rhodococcus coprophilus, Rhodococcus fascians, Rhodococcus marinonascens, Rhodococcus phenolicus,* and *Rhodococcus rhodnii* constitute a third group that forms well-branched substrate mycelia.

The time taken to complete the growth cycle ranges from 24 h in relatively undifferentiated forms, such as *Rhodococcus equi,* to several days for those like *Rhodococcus coprophilus* which show more pronounced morphological differentiation (Locci et al., 1982). The timing of the fragmentation process is influenced by environmental factors (Williams et al., 1976), which may act through their effects on growth rates. Rhodococci do not usually form aerial hyphae; an exception is *Rhodococcus coprophilus* which exhibits feeble aerial hyphae (Locci and Sharples, 1984).

Cell envelope composition. The genus *Rhodococcus* is defined primarily on the basis of wall envelope composition. Rhodococci have (a) a peptidoglycan consisting of *N*-acetylglucosamine, *N*-glycolylmuramic acid, D-and L-alanine, and D-glutamic acid with *meso*-diaminopimelic acid (*meso*-A_2pm) as the diamino acid; (b) arabinose and galactose as diagnostic wall

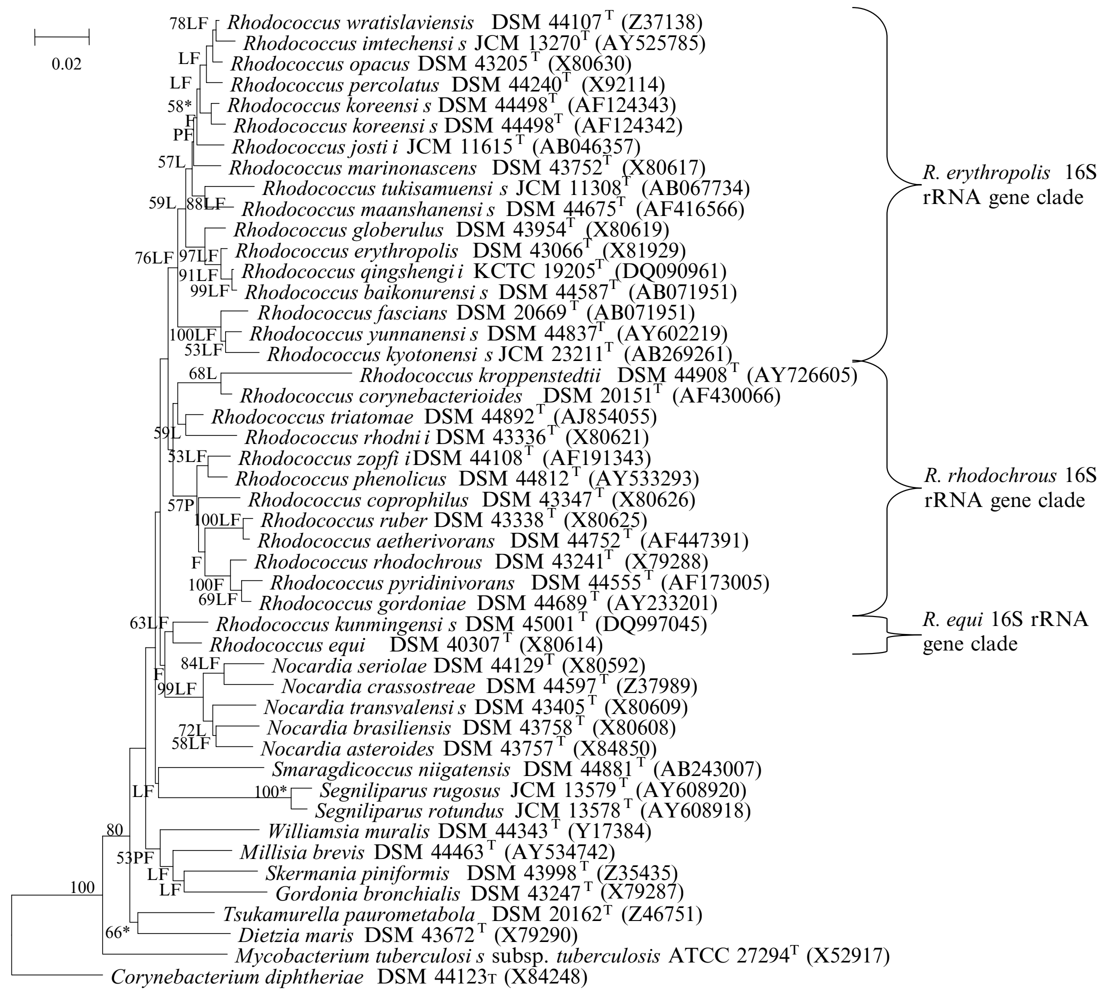

FIGURE 96. Neighbor-joining tree based on early complete 16S rRNA gene sequences showing relationships between *Rhodococcus* species and between them and representatives of other mycolic acid-containing genera classified in the order *Corynebacteriales*. Asterisks indicate branches of the tree that were also found using the least-squares and maximum-parsimony tree-making algorithms. F and L indicates branches that were recovered using the least-squares and maximum-parsimony methods, respectively. The numbers at the nodes indicate the levels of bootstrap support derived from a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. The bar = 0.02 substitutions per nucleotide position.

sugars (i.e., rhodococci have a wall chemotype IV and whole-organism sugar pattern type A *sensu* Lechevalier and Lechevalier, 1970); (c) a phospholipid pattern that includes diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides as major components (i.e., phospholipid pattern type II *sensu* Lechevalier et al., 1977, 1981a); (d) a fatty acid profile consisting of major amounts of straight chain, unsaturated and tuberculostearic acids (i.e., a type IV fatty acid pattern *sensu* Lechevalier et al., 1977); (e) mycolic acids with 30–54 carbon atoms (Minnikin and Goodfellow, 1980, 1981); (f) dihydrogenated menaquinones with eight isoprene units (Collins et al., 1985; Goodfellow and Maldonado, 2006).

Selective ion monitoring gas chromatography-mass spectrometry (SIM GC-MS) analysis yields a much more detailed profile of the mycolic acid composition of rhodococci than GC-MS (Stratton et al., 1999). This structural diversity can be exemplified by the mycolic acids of *Rhodococcus rhodochrous* 11R which were assigned to 60 subgroupings based on α- and β-mycolic acid chain lengths and the degree of unsaturation. They also noted that mycolic acid composition was sensitive to cultural conditions, including carbon source and incubation temperature; hence, there is a need for standardized growth conditions for mycolic acid analyses. A model for the organization of the rhodococcal cell envelope has been proposed in which the mycolic acids (as in other mycolic acid-containing strains) represent an outer lipid permeability barrier (Sutcliffe, 1998). Consistent with this, channel forming proteins have been extracted from rhodococci (Lichtinger et al., 2000; Riess and Benz, 2000; Riess et al., 2003). Mycolic acids are either covalently bound to the peptidoglycan-arabinogalactan skeleton of the cell wall or are extractable (Goodfellow et al., 1976; Sutcliffe, 1997).

Lipoarabinomannan-type lipoglycans have been detected in the type strain of *Rhodococcus rhodnii* (Flaherty et al., 1996). The structure of a truncated lipoarabinomannan, novel lipoglycan, from *Rhodococcus equi* was reported by Garton et al.

(2002). The purified compound, termed ReqLAM, induced an immune response in equine macrophages that was equivalent to *Rhodococcus equi* whole cells suggesting that the early macrophage cytokine response to the bacteria can be attributed to ReqLAM. The structure of a related lipoglycan from *Rhodococcus ruber*, designated RruLAM, was found to be much simpler than that established for *Mycobacterium tuberculosis* lipoarabinomannan and different from that of *Rhodococcus equi* (Gibson et al., 2003). The RruLAm did not induce the production of pro-inflammatory cytokines in either human or murine macrophage cell lines. This suggests that some sophisticated structures, such as phosphoinositol capping motifs, are needed for such activity.

Colony morphology. Rhodococci grow well on standard laboratory media used to cultivate actinomycetes. Colonies may be rough, smooth, or mucoid. They are 0.25–2 mm in diameter, and may be opaque, buff, coral, cream, orange, pink, red, or yellow. Colorless variants occur. Pigmentation may be enhanced by light (Rowbotham and Cross, 1977b).

Nutritional and growth conditions. *Rhodococcus* strains grow well on media such as glucose-yeast extract agars (Gordon and Mihm, 1962a; Waksman, 1950), modified Bennett's agar (Jones, 1949), brain-heart infusion (Difco 0418), and modified Sauton's agar supplemented with thiamine (Mordarska et al., 1972), and Lowenstein-Jensen's medium (BBL 20908). Most strains grow between 15 and 40°C.

Metabolism. The remarkable metabolic diversity shown by rhodococci makes them ideal candidates for enhancing the bioremediation of contaminated sites, and as biocatalysts for a wide range of biotransformations (Beard and Page, 1998; Bell et al., 1998; Finnerty, 1992; Hughes et al., 1998; Warhurst and Fewson, 1994). Consequently, their metabolic diversity is of interest to the chemical, environmental, energy, and pharmaceutical sectors, as well as for applications in the desulfurization of fossil fuels (Matsui et al., 2002), and the industrial production of acrylamide (Hughes et al., 1998). Extensive reviews on the catabolic versatility and enzymic capabilities of rhodococci are available (De Carvalho and da Fonseca, 2005; Gürtler et al., 2004; Larkin et al., 2005, 2006; van der Geize and Dijkhuizen, 2004). Their metabolic diversity is related to the presence and mobilization of large linear plasmids and to multiple homologs of enzymes in catabolic pathways (McLeod et al., 2006; van der Geize and Dijkhuizen, 2004). There is evidence that catabolic genes are co-regulated in separate gene clusters arising from multiple adaptive recombinations (Larkin et al., 2005).

Rhodococcus strains assimilate a broad range of carbohydrates and proteins (Goodfellow and Alderson, 1977; Goodfellow et al., 1982a, 1982c) but also show an exceptional ability to degrade hydrophobic natural compounds and xenobiotics, including aliphatic hydrocarbons, halogenated aliphatic hydrocarbons, polycyclic aromatic hydrocarbons, and nitroaromatic compounds (Armfield et al., 1995; Cain, 1981; Peczynska-Czoch and Mordarski, 1984; Tárnok, 1976), as well as polychlorinated biphenyls (Seto et al., 1995; Warren et al., 2004), a particularly widespread and persistent class of environmental pollutants. Also, some persistent thiocarbonate and *s*-triazine herbicides (De Schrijver and De Mot, 1999) and 2-mercaptobenzothiazole (Haroune et al., 2004), which is used as a vulcanization accelerator in the rubber industry, are catabolized by rhodococci. *Rhodococcus* strains have been implicated in the degradation of lignin-related compounds (Eggeling and Sahm, 1980, 1981; Rast et al., 1980) and humic acid (Cross et al., 1976).

The metabolic versatility of *Rhodococcus* strains can be exemplified by the ability of *Rhodococcus aetherivorans* to degrade *t*-butyl ether (Goodfellow et al., 2004), *Rhodococcus erythropolis* to utilize 1-chlorobutane (Sallis et al., 1990), *Rhodococcus gordoniae* to metabolize very high concentrations of phenol (Jones et al., 2004), *Rhodococcus koreensis* to utilize 2,4-dinitrophenol (Yoon et al., 2000a), *Rhodococcus percolatus* to breakdown 2,4,6-trichlorophenol (Briglia et al., 1996), *Rhodococcus pyridinivorans* to metabolize pyridine (Yoon et al., 2000b), and *Rhodococcus zopfii* to degrade natural estrogens (Yoshimoto et al., 2004). In addition, *Rhodococcus imtechensis* utilizes toxic and recalcitrant compounds, such as *p*-nitrophenol and 2,4-dinitrophenol as sole carbon and energy sources (Ghosh et al., 2006), while *Rhodococcus qingshengii* degrades carbendiazine, a widely used benzimidazole fungicide (Xu et al., 2007), which harms the liver and endocrine system and has mutagenic and teratogenic effects on animals even at low concentrations (Mazellier et al., 2003). *Rhodococcus baikonurensis* metabolizes diesel oil (Lee et al., 2006).

Rhodococcus erythropolis cells and enzymes have been used extensively in bioremediation and biocatalysis studies as they carry out innumerable bioconversions and biodegradations (De Carvalho and da Fonseca, 2005). These organisms, for instance, produce hydrolases which catalyze useful oxidation reactions (Straathof et al., 2002); oxidases for the activation of chemically inert compounds (De Carvalho and da Fonseca, 2005); dehalogenases for the hydrolysis of halogenated compounds (Erable et al., 2005); dehydrogenases for the production of enantiomerically pure products (Schenkels et al., 2001); desulfurases**.** for the removal of sulfur from hydrocarbons, notably fossil fuels (Yu et al., 2006); nitrilases for the production of acrylamide (Yamada and Kobayashi, 1996).

Desulfurizing enzymes remove the sulfur moiety from organosulfur molecules leaving the carbon skeleton intact. Two kinds of desulfurization reactions are recognized (Oldfield et al., 1998). The dibenzothiophene (DBT)-specific pathway desulfurizes DBT to 2-hydroxybiphenyl (2-HBP) and inorganic sulfate, and the benzothiophene (BTH)-specific pathway desulfurizes BTH to 2-(2-hydroxyphenyl) ethan-1-al and probably inorganic sulfate. The DBT-desulfurization pathway was originally identified in "*Rhodococcus rhodochrous*" strain IGTS8 (Kayser et al., 1993), which is now known to be a strain of *Rhodococcus erythropolis* (Oldfield et al., 1998). Several mutant strains of *Rhodococcus erythropolis* ISTS8 have been genetically engineered to increase its ability to carry out desulfurization (Hirasawa et al., 2001; Holland et al., 2003). The influence of operational conditions during batch growth of strain IGTS8 on the desulfurizing capability of cells was studied by del Olmo et al. (2005), who also generated a kinetic model to describe the evolution of desulfurization ability during growth. Two additional *Rhodococcus erythropolis* isolates, strains A66 and A69, like strain IGTS8, desulfurized DBT to 2-HBP, following the 4S pathway of desulfurization (Santos et al., 2007). Extensive

desulfurization of diesel fuels has been achieved using a *Rhodococcus erythropolis* strain isolated from oil contaminated soil (Zhang et al., 2007).

Rhodococci produce enzymes that transform nitrile compounds (Beard and Page, 1998; Brandão et al., 2003; De Carvalho and da Fonseca, 2005; O'Mahony et al., 2005). Two types of enzyme are involved in nitrile biotransformations, nitrilases (which catalyze the direct cleavage of nitriles to the corresponding acids and ammonia) and nitrile hydratases (which catalyze the hydration of nitriles to amides) (Bunch, 1998). The use of enzymes as nitrile-transforming catalysts is attractive economically and environmentally for the production of acrylamide and acrylates, inasmuch as reactions are less severe than those of chemical processes and highly pure products are obtained without the formation of undesirable by-products (Beard and Page, 1998; Hughes et al., 1998; Nagasawa and Yamada, 1989). The nitrile hydratase catalyzed process for the production of acrylamide, which was developed by the Nitto Chemical Industrial Company in collaboration with Kyoto University, was the first successful commercial biocatalyst process involving the production of a commodity chemical. The important features of the early biocatalysts used by Nitto for acrylamide production have been described by Kobayashi et al. (1992).

Improved biocatalysts for acrylamide production sought through the Kyoto/Nitto collaboration led to *Rhodococcus* J1 becoming the third generation biocatalyst for the commercial production of acrylamide from acrylonitrile (Nagasawa et al., 1993). The nitrile hydratase of this organism is a robust and versatile enzyme that is induced when the culture medium is supplemented with cobalt and crotonamide (Nagasawa et al., 1988a, 1988b; Nagasawa and Yamada, 1990; Yamada and Kobayashi, 1996). The nucleotide sequence of the nitrile hydratase of this organism has been determined (Kobayashi et al., 1990). About 30,000 tons of acrylamide are produced using this enzyme every year (Kobayashi and Shimizu, 2000).

Rhodococcus rhodochrous strains have also been highlighted as potential biocatalysts for acrylamide synthesis (Raj et al., 2006; Sankhian et al., 2003), and the nitrile hydratase of a *Rhodococcus rhodochrous* strain has been shown to catalyze the conversion of butyronitrile to butyramide (Raj et al., 2007). *Rhodococcus erythropolis* BL1, an isolate from a marine sediment was found to grow exponentially in the presence of 900 mM acetonitrile. This tolerance of acetonitrile is the highest reported for a nitrile-hydrolyzing bacterium (Langdahl et al., 1996).

Nitrile-degrading rhodococci have been isolated from diverse aquatic and terrestrial habitats (Brandão and Bull, 2003; Brandão et al., 2002; Colquhoun et al., 1998a; Heald et al., 2001; O'Mahony et al., 2005), suggesting that nitrile transforming enzyme activity is geographically widely distributed in nature. Brandão and his colleagues found that most of their nitrile-metabolizing isolates were phylogenetically related to *Rhodococcus erythropolis*, and that the nitrile-transforming enzyme genes of some of their isolates were unique to the geographical region from which they were isolated. In a continuation of these studies, Brandão et al. (2003) found that amidase and nitrile hydratase genes present in geographically distinct *Rhodococcus erythropolis* strains were not globally mixed, thereby raising the prospect that the amino acid variation found for the nitrile hydratases might be used for molecular breeding (Ness et al., 2000; Raillard et al., 2001). They also provided evidence for the coevolution of amidase and nitrile hydratase genes in *Rhodococcus erythropolis*.

Rhodococci are a valuable source of novel bioflocculants and biosurfactants (De Carvalho and da Fonseca, 2005; Kurane et al., 1995; Lang and Philp, 1998; Rapp et al., 1979). *Rhodococcus* strains, for instance, respond to the presence of *n*-alkanes by producing biosurfactants which facilitate the assimilation of hydrophobic compounds as growth substrates (Kurane et al., 1995; Lang and Philp, 1998; Wagner et al., 1983). Particular attention has been paid to trehalose mycolates, notably those from *Rhodococcus erythropolis* (Kretschmer et al., 1982; Uchida et al., 1989). The demand for surfactants can be expected to increase (Desai and Banat, 1997), partly due to the environmental concern associated with the continued use of chemically synthesized components. Rhodococcal surface-active lipids are attractive for certain applications due to their biodegradability, lipophilicity, low toxicity, and nonionic nature, as well as their pH and temperature stability (Rapp et al., 1979; Rapp and Gabriel-Jurgens, 2003; Ristau and Wagner, 1983). Bioflocculants are used to flocculate a diverse range of solids (Kurane and Tomizuka, 1992).

Rhodococcus strains are a potential source of carotenoid pigments, which are used in the food industry as colorants. *Rhodococcus erythropolis* naturally synthesizes monocyclic carotenoids, namely 4-keto-γ-carotene and γ-carotene (Tao et al., 2004). In a continuation of this study, the β-carotene desaturase gene (*crtU*) from *Brevibacterium linens* was expressed in *Rhodococcus erythropolis* to produce chlorobactene, an asymmetric aryl carotenoid which has a similar structure to the food colorant isorenieratene (Tao et al., 2006). Growth of the engineered strain in eight media showed that nutrient broth-yeast extract medium supplemented with fructose gave the highest yield of chlorobactane. This compound has potential as a colorant that gives a different shade of color than isorenieratene and its hydroxyl derivatives (Dufossé et al., 2001).

Genetics. Initial developments in rhodococcal genetics have been the subject of several extensive reviews (Adams and Brownell, 1976; Brownell, 1978; Brownell and Denniston, 1984; Finnerty, 1992). The emphasis in these pioneering studies was on *Rhodococcus erythropolis*. Indeed, as early as 1963, a recombination system was demonstrated in strains now assigned to this taxon. Over 60 genetic traits were used to construct a *Rhodococcus erythropolis* linkage map, and temperate phages were introduced as cloning vectors for a gene cloning system (Adams, 1964; Adams and Bradley, 1963; Brownell and Denniston, 1984; Brownell et al., 1982). The flexibility of the *Rhodococcus* genome with respect to recombination was demonstrated in studies of plasmid integration in *Rhodococcus fascians* (Desomer et al., 1991).

Rhodococcus strains have been shown to contain plasmids which range from small cryptic closed circular molecules to large linear plasmids (Gürtler et al., 2004; Larkin et al., 1998, 2005; Letek et al., 2008; Matsui et al., 2007; van der Geize and Dijkhuizen, 2004). *Rhodococcus rhodochrous* B-276, which is used commercially for chiral epoxide production (Furuhashi, 1992) contains four circular cryptic plasmids (Saeki, 1998) and four-linear megaplasmids (Saeki et al., 1999). Well characterized circular plasmids are associated with the pathogenicity

determinants of *Rhodococcus equi* (Takai et al., 1991, 1993, 1995) and with the degradation of organic pollutants (Dabbs, 1998). The *Rhodococcus equi* virulence plasmids are representative of a new family of actinobacterial plasmids which combine plasmid-specific insertions with a conserved backbone structure linked to plasmid maintenance and transfer (Letek et al., 2008). Circular plasmids of rhodococci have been shown to code for diphenyl metabolism (Masai et al., 1997), chloroalkane degradation (Kulakov et al., 1997), dibenzothiophene desulfurization (Denis-Larose et al., 1997), 2-methylaniline metabolism (Schreiner et al., 1991) and propene degradation (Matsui et al., 2007).

The remarkable catabolic diversity of rhodococci can be partly attributed to the presence and mobility of large linear plasmids. The genome of the most effective degrader of polychlorinated biphenyls, *Rhodococcus* RHA1, consists of a chromosome and three large linear plasmids, pRHL1 (1100 kb), pRHL2 (450 kb), and pRHL3 (330 kb) (McLeod et al., 2006). Most of the genes of the upper biphenyl catabolic pathway are located on the two largest linear plasmids (Shimizu et al., 2001). Genes that encode related isozymes are scattered throughout the genome, as are those involved in the degradation of benzoates and 2-hydroxypenta-2,4-dienoate. The complete annotated sequence of pRHL3 indicates that it is a typical actinomycete invertron which contains large terminal inverted repeats with a tightly associated protein (Warren et al., 2004).

Other plasmid-borne catabolic plasmids have been detected in rhodococci. *Rhodococcus erythropolis* IGTS8 has a large plasmid (150 kb) that is involved in the desulfurization of organosulfur compounds (Denis-Larose et al., 1997) while the genes responsible for the oxidation of isopropylbenzene in *Rhodococcus erythropolis* are encoded on the linear plasmid pBD2 (Stecker et al., 2003). *Rhodococcus erythropolis* PR4, an alkane-degrading organism, contains one linear plasmid, pREL 1 (271 kb), and two circular plasmids, pREC1 and pREC2 (Sekine et al., 2006). The linear plasmid contains several regions homologous to plasmid pBD2 of *Rhodococcus erythropolis* BD2. Other large linear plasmids of rhodococci encode genes for the catabolism of alkylbenzene (Kim et al., 2002a), biphenyl (Taguichi et al., 2004), naphthalene (Kulakov et al., 2005), toluene (Priefert et al., 2004), and chloroaromatic compounds (Konig et al., 2004).

Several rhodococcal megaplasmids have been found to be conjugative (Dabrock et al., 1994; Desomer et al., 1988; Kalkus et al., 1993; Priefert et al., 2004; Shimizu et al., 2001). Sequences and gene annotations are available for megaplasmids, including p33701 from *Rhodococcus equi* ATCC 33701 (Takai et al., 2000b), pBD2 from *Rhodococcus erythropolis* BD2 (Stecker et al., 2003), pRHL from *Rhodococcus* RHA1 (Warren et al., 2004), and pREC1 and pREL2 from *Rhodococcus erythropolis* PR4 (Sekine et al., 2006). A single-strand DNA transfer system similar to other bacterial conjugative systems may function in the transfer of rhodococcal megaplasmids. Conjugative plasmids have been detected in *Rhodococcus erythropolis* AN12 (Yang et al., 2007).

Genetic tools have been developed to exploit the metabolic potential of rhodococci (Finnerty, 1992; Larkin et al., 1998): these include *Escherichia coli*–*Rhodococcus* shuttle vectors (De Mot et al., 1997; Hirasawa et al., 2001; Mangan et al., 2005; Matsui et al., 2006, 2007; Shao et al., 1995) and a gene description system (van der Geize et al., 2000). The pNC903-derived *Rhodococcus*–*Escherichia coli* shuttle vectors pNC9501 and pNC9503 have been used for the production of poly (3-hydroxyalkanoic acids) in *Rhodococcus opacus* PD630 (Kalscheuer et al., 1999). Integrative elements of the L1 mycobacteriophage have been used to transpose *Rhodococcus rhodnii*, a symbiont of the Chagas disease vector *Rhodnius prolixus* (Dotson et al., 2003). A transposon mutagenesis system has also been developed for *Rhodococcus equi* (Mangan and Meijer, 2001), along with targeted mutagenesis systems (Jian et al., 2003; Navas et al., 2001). Cloned and characterized amidase and nitrile hydratase genes from rhodococci have been expressed in *Escherichia coli* (Hashimoto et al., 1991; Ikehata et al., 1989; Kobayashi et al., 1991).

A multipurpose transposon-based vector system which mediates protein expression in *Rhodococcus erythropolis* was designed by Sallam et al. (2007). Inducible expression vectors operative in several *Rhodococcus* species have been constructed (Nakashima and Tamura, 2004a, 2004b). These workers reported expression yields of recombinant proteins up to 10 mg per liter of *Rhodococcus erythropolis* culture; they also found that some proteins were successfully expressed in *Rhodococcus erythropolis* but not in *Escherichia coli*. In addition, Tn*5* transposition complexes have been used to construct a *Rhodococcus rhodochrous* insertion library of 1500 mutants (Fernandez et al., 2001). Enhanced desulfurization has been reported in a transposon-mutant strain of *Rhodococcus erythropolis* (Watanabe et al., 2003).

It is apparent that rhodococci have large genomes, as exemplified by the complete genome sequences of *Rhodococcus aetherivorans* K4 (7 Mb), *Rhodococcus equi* (5 Mb), *Rhodococcus erythropolis* PR4 (9.7 Mb), and *Rhodococcus* RHA1 (McLeod et al., 2006; van der Geize and Dijkhuizen, 2004; http://www.sanger.ac.uk). Analyses of these and additional whole genome sequences will help unravel the basis of catabolic complexity and diversity shown by rhodococci and will facilitate the construction of *Rhodococcus* strains for biotechnological and environmental applications. Similarly, the application of effective genetic tools for rhodococci, such as unmarked gene deletion and transposon-complex based methods, will promote rational cell engineering. This, in turn, will lead to the exploitation of rhodococcal catabolic diversity by allowing the overexpression of key catabolic pathways and enzymes, and the optimization of biocatalytic properties through the inactivation of undesirable enzymes and pathways.

Equine *Rhodococcus equi* virulence is positively correlated with the expression of the *vapA* gene (Haites et al., 1997; Morton et al., 2001; Takai et al., 1991, 1993; Tkachuk-Saad and Prescott, 1991), which is located on a ca. 85-kb plasmid, the virulence-associated plasmid (Takai et al., 2000a). The *vap* operon of equine isolate ATCC 33701 is situated within a 27,500-bp pathogenicity island and encodes the functional genes, *vapA, vapC, vapD*, and *vapE*. Immunoblotting studies (Byrne et al., 2001) show that the gene products, VapA (a cell-surface lipoprotein) and VapC, VapD, and VapE (all secreted proteins) are expressed during growth at 37°C, and expression of these proteins at 37°C is consistent with their roles in virulence. The *vapA* gene from

Rhodococcus equi ATCC 33701 has been sequenced and encodes a 17.4-kDa polypeptide (Sekizaki et al., 1995). A variant of *vapA*, known as *vapB* (Byrne et al., 2001; Takai et al., 2000a), has been detected in some *Rhodococcus equi* isolates from pigs. The *vapB* gene from *Rhodococcus equi* A5, isolated from an AIDS patient, has been sequenced and encodes a 18.2-kDa polypeptide (Sekizaki et al., 1995). The sequence of a *vapB* associated plasmid has been determined and confirms that the Vap family of proteins is unique to *Rhodococcus equi* and is carried in a pathogenicity island inserted into a conserved plasmid backbone (Letek et al., 2008).

Until recently, a major bottleneck in *Rhodococcus equi* research was a dearth of suitable genetic tools. However, electroporation protocols are now available for introducing DNA into *Rhodococcus equi* strains (Sekizaki et al., 1998; Zheng et al., 1997), and procedures for random and targeted mutagenesis have been developed (Ashour and Hondalus, 2003; Jian et al., 2003; Mangan and Meijer, 2001; Navas et al., 2001). Several *Rhodococcus equi–Escherichia coli* shuttle vectors have been described, including a plasmid based on the origin of replication of the *Rhodococcus equi* virulence plasmid (Zheng et al., 1997), and a plasmid that has only been found in *Rhodococcus fascians* (Sekizaki et al., 1998). In addition, versatile *Rhodococcus equi–Escherichia coli* shuttle vectors are available for the analysis of gene function in *Rhodococcus equi* (Mangan et al., 2005). Even so, there is a need for integrative plasmids for the analysis of virulence of *Rhodococcus equi* in mice and foals.

Preliminary analysis of a partial genome sequence of *Rhodococcus equi* ATCC 33201 has revealed a number of interesting features, notably the extent of the homology of genes identified with those of *Mycobacterium tuberculosis* (Rahman et al., 2003). Striking similarities were found in the proportion of genes devoted to fatty acid degradation and to lipid biosynthesis. The *Rhodococcus equi* strain contained homologs of many of the genes of putative or proven importance in *Mycobacterium tuberculosis* thereby emphasizing the need to understand the basis of virulence in this organism. Comparative genomics will be greatly assisted by the completion of the 5-Mb genome sequence of *Rhodococcus equi* strain 103 by the Sanger Institute (http://www.sanger.ac.uk).

Antibiotic sensitivity. Most rhodococci are sensitive to antibacterial antibiotics such as aminoglycosides, cephalosporins, macrolides, penicillins, and tetracyclines, less sensitive to sulfonamides, and resistant to most antitubercular compounds (Goodfellow et al., 1982a; Goodfellow and Orchard, 1974; Helmke and Weyland, 1984; McNeil and Brown, 1994; Rowbotham and Cross, 1977b). They are also sensitive to lysozyme (Goodfellow, 1971; Mordarska et al., 1978). Conflicting results recorded for *in vitro* sensitivity studies on *Rhodococcus equi* can be attributed to factors such as variability in testing protocols and differences in tested populations of isolates. However, *Rhodococcus equi* strains are susceptible to amoxycillin–clavulanate, ampicillin–sulbactam, gentamicin, and imipenem, but tend to be resistant to amoxicillin, clindamycin, oxacillin, and penicillin (McNeil and Brown, 1992). They have also been reported to show a high degree of resistance to sulfonamides (Barton and Hughes, 1980; Woolcock and Mutimer, 1980).

Pathogenicity. *Rhodococcus equi* is a facultative intracellular pathogen which can infect a wide range of animals, but it is primarily a pathogen of foals (Barton and Hughes, 1980; Prescott, 1991). Indeed, it is considered to be the most significant pathogen of the equine breeding industry (Takai et al., 1995). The primary clinical manifestation of *Rhodococcus equi* infections in foals is severe suppurative bronchopneumonia. The prevalence and fatality rates of *Rhodococcus equi* pneumonia are high (Prescott, 1991; Takai et al., 1995), and there is evidence that pneumonia caused by this organism reduces the racing performance of foals (Ainsworth et al., 1998). The primary source of the organism is soil (Takai, 1997; Takai et al., 1986). Inhalation of *Rhodococcus equi* is probably the main route of exposure in foals (Barton and Hughes, 1980; Prescott, 1991).

The typical manifestation of *Rhodococcus equi* pneumonia is as a chronic suppurative bronchopneumonia with extensive abscess formation and associated lymphadenitis (Barton and Hughes, 1980; Prescott, 1991; Zink et al., 1986). Foals are typically affected within 1–5 months of birth. Although unknown, the predisposition of foals to infection within this age range is thought to be related to the relative immaturity of the immune system of individual foals (Chaffin et al., 2004; Darrah et al., 2004; Hooper-McGrevy et al., 2001). A more acute, but less common, form of *Rhodococcus equi* pneumonia involves the death of foals within a few hours or days of showing signs of respiratory distress. *Rhodococcus equi* has occasionally been implicated in equine abortion and placentitis (Patterson-Kane et al., 2002).

Nearly all strains isolated from affected foals contain the virulence 80–90-kb plasmid which carries the gene that encodes the 15–17-kDa protein, VapA (Takai, 1997; Takai et al., 1993). In non-equine animal hosts, the variant plasmid encoding VapB has been identified (Byrne et al., 2001; Letek et al., 2008; Oldfield et al., 2004; Takai et al., 2000a). Strains which lack VapA/B proteins are relatively common in non-equine isolates (Meijer and Prescott, 2004); such strains may carry other types of *Rhodococcus equi* virulence–extrachromosomal replicons (Ocampo-Sosa et al., 2007).

Rhodococcus equi infections of animals other than horses are rare. Nevertheless, such infections have been recorded in many animals, including buffaloes, cattle, cats, crocodiles, deer, dogs, goats, koala bears, marmosets, pigs, seals, sheep, and wild birds (Farias et al., 2007; Muscatello et al., 2007b; Walsh et al., 1993). An increasing number of *Rhodococcus equi* infections are being reported in cats and dogs (Takai et al., 2003) and goats (Kabongo et al., 2005; Tkachuk-Saad et al., 1998). In cats, pyrogranulomatous lesions are characteristic symptoms of *Rhodococcus equi* infections with primary involvement in the extremities (Patel, 2002). In cattle and pigs, the organism causes lymphadenitis (Karlson et al., 1940; Katsumi et al., 1991; Soedarmanto et al., 1997). The lesions observed in cases of lymphadenitis resemble those of tuberculosis, thereby causing a problem in the diagnosis of tuberculosis (Mutimer et al., 1982; Mutimer and Woolcock, 1980).

Rhodococcus equi is being increasingly recognized as a pathogen of immunocompromised humans, especially patients with AIDS (Harvey and Sunstrum, 1991; Lasky et al., 1991; Samies

et al., 1986; Scott et al., 1995). The clinical presentation of rhodococcal infections in humans is influenced by the immune status of the host and the virulence of the causal agent. The first documented human infection involved a patient suffering from *Rhodococcus equi* pneumonia who had been given corticosteroid therapy for chronic hepatitis (Golub et al., 1967). The organism is now typically seen as an agent of invasive pulmonary infections in severely immunosuppressed patients, particularly those with acquired immune deficiency syndrome (Arlotti et al., 1996; McNeil and Brown, 1994; Weinstock and Brown, 2002). Indeed, *Rhodococcus equi* pneumonia has become a disease of increasing significance in human medicine partly as a consequence of the AIDS pandemic (Kedlaya et al., 2001; Kwak et al., 2002; Linder, 1997). However, *Rhodococcus equi* infections are varied, ranking from localized infections (secondary to trauma) to fatal systemic infections (Kamboj et al., 2008; Kohl and Tillmanns, 2002; Napoleão et al., 2005; Nasser and Bizri, 2001; Verville et al., 1994). The first lethal case of *Rhodococcus equi* infection in a previously healthy person was reported by Gabriels et al. (2006). It seems likely that the incidence of human infection caused by *Rhodococcus equi* has been underestimated due to either misdiagnosis or unwarranted discarding of the organism as a contaminant diphtheroid (Weinstock and Brown, 2002).

The *Rhodococcus equi choE* gene, a chromosomal locus that encodes cholesterol oxidase (Navas et al., 2001), is considered to be a major virulence factor of *Rhodococcus equi* (Hondalus, 1997). ChoE is the membrane-damaging factor responsible for the characteristic shovel-shaped synergistic hemolysis [CAMP-like (acronym for "Christie–Atkins–Munch–Petersen")] reaction elicited by *Rhodococcus equi* in the presence of sphingomyelinase C-producing bacteria, such as *Bacillus cereus, Listeria ivanovii*, and *Staphylococcus aureus* (Navas et al., 2001). This CAMP-like reaction can be used as a phenotypic marker for the rapid identification of *Rhodococcus equi* (Ripio et al., 1995).

The basis of pathogenicity of *Rhodococcus equi* is its ability to replicate in alveolar macrophages (Hondalus and Mosser, 1994). This is dependent on its capacity to interfere with endosomal maturation following phagocytosis and to prevent acidification of the vacuole in which it resides (Fernandez-Mora et al., 2005; Toyooka et al., 2005; Zink et al., 1987). Intracellular proliferation of the pathogen eventually results in the death of the macrophage, and associated massive damage to lung tissue characterized by cavitation and granuloma formation (Lührmann et al., 2004; Meijer and Prescott, 2004). The availability of the complete genome sequence for *Rhodococcus equi* will significantly advance understanding of the molecular basis of its virulence.

A number of other rhodococcal species have been implicated as agents of human disease, including *Rhodococcus erythropolis, Rhodococcus globerulus, Rhodococcus luteus, Rhodococcus rhodnii, Rhodococcus rhodochrous*, and *Rhodococcus ruber* (Alture-Weber et al., 1968; Cuello et al., 2002; Gugnani et al., 1998; Haburchak et al., 1978; Lalitha et al., 2006; von Below et al., 1991). Information about the potential virulence of these organisms is limited, though it is known that immunosuppressed guinea pigs inoculated with *Rhodococcus* spp. develop visible granulomas (Haburchak et al., 1978). However, Osoagbaka (1989) found that *Rhodococcus ruber* isolated from human sputa and inoculated into immunosuppressed mice produced a pathological response in the lungs similar to that observed in humans. Mycolyl glycolipid fractions purified from *Rhodococcus ruber* have been shown to induce granuloma formation in immunosuppressed mice (Matsunaga et al., 1996; Yasuda, 1999). In addition, a *Rhodococcus* strain has been implicated as the cause of septic arthritis and osteomyelitis in a healthy, immunologically normal young girl (Broughton et al., 1981).

The type strain of *Rhodococcus corynebacteroides* was used as a substitute for *Mycobacterium tuberculosis* to identify the antigen responsible for adjuvant arthritis (Riess and Benz, 2000). This means that this organism contributes to an understanding of this disease, which shares some features common with rheumatoid arthritis of man (Paronetto, 1970, 1972). Thus, *Rhodococcus corynebacteroides* may provide a clue to the etiology of human arthritis (Lorentzen, 1999).

Rhodococcus fascians is a soil borne organism that infects numerous plants, inducing the formation of leafy galls, fasciation, and witch's broom (Goethals et al., 2001; Temmerman et al., 2000; Vereecke et al., 2000). It is a well adapted epiphyte that colonizes inner tissues and plant surfaces (Cornelis et al., 2001, 2002). One of the most severe symptoms of *Rhodococcus fascians* infections is the formation of leafy galls. These are proliferating masses of meristematic tissue that are covered with very short hypertrophied shoots that appear at the crown of infected plants (De O. Manes et al., 2001; Lacey, 1936; Vereecke et al., 2000). The severity of the disease symptoms induced by the organism depends upon the age and type of the plant and on the inoculation method (Lacey, 1939; Vereecke et al., 2000). Symptom persistence depends upon the continued presence of the bacteria (Lacey, 1936).

Extensive studies on the molecular basis of the *Rhodococcus fascians*-plant interaction have shown that the virulence determinants are located on a linear plasmid, pFi D188 (Crespi et al., 1992, 1994; Stange et al., 1996; Temmerman et al., 2000; Vereecke, 1997). Two bacterial loci, *att* and *fas*, are required for full virulence (Cornelis et al., 2002). The *att* operon is involved in the biosynthesis of regulatory compounds that are necessary to induce *att* and *fas* gene expression and are induced during the interaction with the plant (Maes et al., 2001). The *fas* operon encodes proteins, including an isopentenyl transferase (IPT) which is involved in the biosynthesis of a compound that shows cytokinin activity (Crespi et al., 1992, 1994; Temmerman, 2000); the IPT is homologous to isopentenyl transferases found in *Agrobacterium tumefaciens* and *Pseudomonas syringae* pv. *savastanoi* (Crespi et al., 1992). It is thought that novel compounds produced by *Rhodococcus fascians* help disrupt plant hormone balances eventually leading to disease (Vereecke et al., 2000). Temmerman et al. (2000) isolated an AraC-type regulatory gene, *fasR*, located on the linear plasmid pFID188, which was indispensible for pathogenesis and *fas* gene expression. They also found that expression of the *fas* genes is controlled at both transcriptional and the translation levels.

Ecology. Rhodococci are common in aquatic and terrestrial habitats (Brandão et al., 2002; Cross et al., 1976; Goodfellow and Williams, 1983; Jiang and Xu, 1996). They have been isolated from soil, freshwater, and marine sediments, and from

the gut contents of blood-sucking arthropods with which they may form mutualistic associations (Colquhoun et al., 1998b; Goodfellow and Aubert, 1980; Yassin, 2005; Zhang et al., 2002). However, relatively little is known about the numbers and activities of rhodococci in natural habitats, though it seems likely they are involved in the metabolism of recalcitrant compounds and xenobiotics (De Carvalho and da Fonseca, 2005; Larkin et al., 2005).

It seems likely that rhodococci contribute to foaming in activated sludge plants (Goodfellow et al., 1996; Lemmer and Kroppenstedt, 1984; Mori et al., 1988; Sezgin et al., 1988), especially in non-filamentous foams (Lemmer et al., 1998). Genus-specific 16S rRNA targeted oligonucleotide probes, Rco 1 and Rco 2, have been designed and used to detect rhodococci in activated sludge foam samples by confocal laser scanning microscopy (Davenport et al., 1998). Quantitative fluorescent *in situ* hybridization (FISH) has been used to examine the relationship between foaming and the concentration of mycolic acid-containing actinomycetes in a 20 m^3 completely mixed activated sludge plant (Davenport et al., 2000). The threshold foaming concentration of the organisms was about 2×10^6 cells/ml or 4×10^{12} cells/ml^2. Mycolic acid-containing bacteria are not readily permeabilized by conventional FISH procedures, but effective protocols have been devised for this purpose (Davenport et al., 2000; Macnaughton et al., 1994).

Rhodococcus coprophilus has been the subject of the most extensive ecological studies (Rowbotham and Cross, 1977a). This organism grows on herbivorous dung and high numbers have also been reported from grazed pastures and from streams, rivers, and lake muds that receive run-off from dairy farms. It seems that the coccoid survival stage contaminates grass in pastures or hay used for fodder, and remains viable after ingestion and passage through the rumen. A significant correlation found between the numbers of *Rhodococcus coprophilus* and fecal streptococci in polluted water led Al-Diwany and Cross (1978) to suggest that the organism might be an effective indicator of farm animal effluent, a view shared by other workers (Mara and Oragui, 1981; Oragui and Mara, 1985).

Little is known about the ecology of most other *Rhodococcus* species, though *Rhodococcus equi* has a worldwide distribution, notably in the feces and environment of horses (Barton and Hughes, 1980; Prescott, 1991; Takai et al., 2006). However, its natural habitat is soil, especially ones enriched with fecal material from domestic and wild animals (Takai et al., 1986). *Rhodococcus erythropolis, Rhodococcus rhodochrous,* and *Rhodococcus ruber* have also been isolated from soil (Goodfellow and Williams, 1983), *Rhodococcus gordoniae, Rhodococcus imtechensis,* and *Rhodococcus qingshengii* from contaminated land sites (Ghosh et al., 2006; Jones et al., 2004; Xu et al., 2007), *Rhodococcus koreensis* and *Rhodococcus pyridinivorans* from industrial wastewaters (Yoon et al., 2000a, 2000b), and *Rhodococcus marinonascens* from marine sediments (Helmke and Weyland, 1984). Other rhodococcal species have been recovered from more specialized locations, as exemplified by the isolation of *Rhodococcus baikonurensis* from the Mir space station (Li et al., 2004c), *Rhodococcus jostii* from a medieval grave (Takeuchi et al., 2002), *Rhodococcus kunmingensis* from the rhizosphere of *Taxus chinensis* (Wang et al., 2008), and *Rhodococcus coprophilus, Rhodococcus equi, Rhodococcus erythropolis, Rhodococcus rhodochrous,* and *Rhodococcus ruber* from activated sludge foam (Lemmer and Kroppenstedt, 1984; Sezgin et al., 1988).

Enrichment and isolation procedures

Rhodococci have been isolated from environmental samples, notably soil, using numerous nutrient media. These include Czapek's agar (Higgins and Lechevalier, 1969), glycerol agar (Gordon and Smith, 1953), glycerol-asparagine agar (Shirling and Gottlieb, 1966), modified Sauton's agar (Mordarska et al., 1972), and Winogradsky's nitrate medium (Winogradsky, 1949). A range of novel rhodococci were isolated by Colquhoun and her colleagues (1998b) from N.W. Pacific Ocean sediments using M3 agar (Rowbotham and Cross, 1977b) and Munz agar supplemented with 1%, v/v paraffin (Nesterenko et al., 1978a). Potato glucose agar has been used to isolate rhodococci from diseased sweet peas (Tilford, 1936). Micromanipulation procedures have been used to isolate rhodococci from activated sludge foams (Soddell et al., 1992).

Rhodococcus coprophilus has been isolated from aquatic and terrestrial habitats by plating heat pretreated environmental samples onto M3 agar and incubating at 30°C for 7 d (Rowbotham and Cross, 1977a). Samples (2 ml) of cream, milk, or water in 100 × 12 mm glass tubes sealed with silicon rubber bungs are heated in a water bath for 6 min at 55°C, then either further diluted or plated out; water samples are stored at 4°C before heating. Suspensions of dung, grass, soil (1:10), or hay (1:50) are homogenized in ¼ strength Ringer's solution containing gelatin (0.01%), pH 7.0, heat pretreated. They are then shaken on a Vortex mixer and 0.2 ml portions spread over M3 agar plates.

A broad range of nutrient media have been used to isolate members of individual rhodococcal species from diverse habitats. *Rhodococcus luteus* was isolated from soil and the skin and intestinal contents of carp on mineral salts agar supplemented with *n*-alkanes following incubation at 28°C (Nesterenko et al., 1982), *Rhodococcus imtechensis* from pesticide-contaminated soil using tryptone soy agar (Ghosh et al., 2006), and *Rhodococcus jostii* from skeletal remains using peptone-yeast extract agar (Takeuchi et al., 2002). *Rhodococcus marinonascens* was obtained by plating suspensions of marine sediments onto rich nutrient media supplemented with seawater and incubating for 8–12 weeks at 18°C (Helmke and Weyland, 1984; Weyland, 1969, 1981). *Rhodococcus kunmingensis* was obtained by suspending air-dried, rhizosphere soil in phosphate buffer containing sodium cholate, incubating at 45°C for an hour, centrifuging the preparation prior to plating out 0.1 ml of the supernatant in 9 ml of sterile buffer onto humic acid-vitamin-gellan gum, and incubating at 28°C for 30 d (Suzuki et al., 1999).

Several procedures have been recommended for the isolation of *Rhodococcus equi* from environmental samples and clinical material (Makrai et al., 2005; Muscatello et al., 2007a). A selective medium (NANAT) supplemented with cycloheximide, nalidixic acid, novobiocin, and potassium tellurite has been used to good effect for this purpose (Muscatello et al., 2007a; Mutimer and Woolcock, 1980; Woolcock et al., 1979). Similarly, *Rhodococcus equi* has been isolated from soil using selective enrichment broth (TANP broth) containing

cycloheximide, nalidixic acid, penicillin, and potassium tellurite prior to subculturing onto M3 medium supplemented with potassium tellurite (Barton and Hughes, 1981). An alternative medium for the isolation of *Rhodococcus equi* was developed by von Graevenitz and Punter-Streit (1995). This medium, (CAZ-NB), consisted of a Mueller-Hinton agar base supplemented with ceftazidine (20 µg per ml) and novobiocin (25 µg per ml). Compared to NANAT, a modified version of this medium supported the growth of significantly higher numbers of virulent *Rhodococcus equi* from soil (Muscatello et al., 2007a).

Numerous enrichment procedures have been used to isolate rhodococci from environmental samples. *Rhodococcus aetherivorans* was isolated from methyl *t*-butyl ether enrichments of petrochemical sludge obtained from a chemical effluent plant (Goodfellow et al., 2004; Salanitro et al., 1994), *Rhodococcus erythropolis* from a discharge point of an industrial site polluted with haloalkanes using a defined growth medium and 1-chlorobutane as sole carbon and energy source (Sallis et al., 1990), and *Rhodococcus percolatus* from a 2,4,6-trichlorophenol fed percolator using minimal salts medium K-N (Briglia et al., 1996; Sundman, 1964). Similarly, *Rhodococcus pyridinivorans* was isolated from industrial wastewater using a minimal salts medium supplemented with a trace element solution and pyridine. The culture was incubated at 30°C on a horizontal shaker for several days when a suspension was transferred to a batch of fresh medium and incubated as before; after three successive transfers, the suspension was plated onto solid media containing pyridine (Yoon et al., 2000c).

Maintenance procedures

Short-term storage can be achieved by serial transfer on standard media, such as modified Bennett's (Jones, 1949) and glucose-yeast extract (Gordon and Mihm, 1962a) agar slopes with storage between transfers at 4°C. Lyophilization, storage in liquid nitrogen, or frozen glycerol suspensions can be used for long-term storage. For lyophilization, cells are suspended in a suitable fluid such as glucose serum (7.5%, w/v) or skimmed milk plus glucose (7.5%, w/v). For storage in liquid nitrogen, the micro-organisms are inoculated into small test tubes containing an appropriate medium and incubated until good growth is visible. The tubes are then closed with cotton wool plugs, dipped in liquid paraffin wax, and placed in a liquid nitrogen container. Glycerol suspensions are prepared by scraping biomass from heavily inoculated agar plates and making suspensions in 3 ml of aqueous glycerol in small vials which are then stored at –20°C (Wellington and Williams, 1978). The frozen glycerol suspensions not only serve as a long-term means of preservation but as a quick source of inoculum. Working inocula are obtained by thawing suspensions at room temperature prior to treating. After use, glycerol suspensions are promptly frozen and stored again at –20°C.

Differentiation of the genus *Rhodococcus* from other genera

The genus *Rhodococcus* can be distinguished from other genera classified in the order *Corynebacteriales* by using a judicious selection of chemotaxonomic and morphological markers (Table 29, in the order *Corynebacteriales*, above), by 16S rRNA gene sequencing (Goodfellow and Maldonado, 2006), by partial sequencing of ribosomal protein AT-L30 (Ochi, 1995), and by quantitative fatty acid analysis (McNabb et al., 1997). Preliminary evidence suggests that carbon utilization tests (Biotype 100 strips) may be useful in separating members of the genera *Dietzia, Gordonia*, and *Rhodococcus* (Bizet et al., 1997). Representatives of these genera have also been distinguished by mycolic acid profiles generated by gas chromatography and mass spectrometry (Nishiuchi et al., 2000). DNA amplification and restriction endonuclease analysis has been used for the identification of clinically significant aerobic actinomycetes, including *Rhodococcus equi* strains (Steingrübe et al., 1997).

Taxonomic comments

The long and chequered taxonomic history of the genus *Rhodococcus* has been considered in several review articles (Bousfield and Goodfellow, 1976; Goodfellow et al., 1998a; Goodfellow and Cross, 1984; Goodfellow and Wayne, 1982). The genus was proposed by Zopf (1891) for two species of red bacteria described by Overbeck (1891) known as *Micrococcus erythromyxa* and *Micrococcus rhodochrous*. The genus, with *Rhodococcus rhodochrous* as the type species, was recognized in the first four editions of *Bergey's Manual of Determinative Bacteriology* (Bergey et al., 1923, 1925, 1930, 1934), but in the following two editions rhodococcal species were classified in the genus *Micrococcus* (Bergey et al., 1939; Breed et al., 1948). However, around this time rhodococcal-like strains were assigned to a plethora of morphologically defined genera. Indeed, only with dramatic improvements in the classification of Gram-stain-positive cocci, which stemmed from the application of chemotaxonomic and numerical taxonomic procedures, was the genus *Rhodococcus* seen to be a recognizable taxon of actinomycetes of agricultural, clinical, and industrial importance (Finnerty, 1992).

The epithet *rhodochrous* (Zopf 1891) was reintroduced by Gordon and Mihm (1957) for a group of actinomycetes that carried a multiplicity of generic and species names and which shared many properties in common with both mycobacteria and nocardiae. This presumptive new species was provisionally assigned to the genus *Mycobacterium* primarily on the basis of colony morphology and staining properties (Gordon, 1966). It soon became evident that *Mycobacterium rhodochrous* formed a recognizable, but heterogeneous taxon, which could be readily distinguished from the genera *Corynebacterium, Mycobacterium*, and *Nocardia*. Evidence to this effect came from several sources, including antibiotic sensitivity (Goodfellow and Orchard, 1974), chemotaxonomic (Alshamaony et al., 1976a, 1976b; Collins et al., 1977), and numerical taxonomic studies (Goodfellow, 1971; Goodfellow et al., 1974; Tsukamura et al., 1979).

The genus *Rhodococcus* was finally resurrected and redefined for rhodochrous strains by Tsukamura (1974) and Goodfellow and Alderson (1977), respectively. The reintroduction of the genus *Rhodococcus* represented a significant milestone in the systematics of mycolic acid-containing bacteria (Goodfellow et al., 1998a, 1999; Goodfellow and Maldonado, 2006).

The taxonomic status of most of the 16 *Rhodococcus* species recognized in the current edition of *Bergey's Manual of Systematic Bacteriology* (Goodfellow, 1989) is underpinned by a wealth of chemotaxonomic (Minnikin and Goodfellow, 1980), DNA–DNA pairing (Mordarski et al., 1980, 1981; Zakrzewska-Czerwinska et al., 1988), and numerical taxonomic data (Goodfellow and Alderson, 1977; Goodfellow et al., 1982c, 1990; Tsukamura, 1974, 1982a).

The genus *Rhodococcus* automatically became a more homogeneous taxon with the reintroduction of the genus *Gordonia* (Stackebrandt et al., 1988) and the proposal for the recognition of the genus *Dietzia* (Rainey et al., 1995c). The improved classification of the genus provided a sound framework for the recognition of additional *Rhodococcus* species. The genus encompasses 30 validly described species with most of the recent ones delineated using a rich mix of genotypic and phenotypic data (Goodfellow et al., 2004; Mayilraj et al., 2006; Wang et al., 2008; Xu et al., 2007). It can be anticipated that many additional rhodococcal species will be proposed in the future as there is evidence that the genus is underspeciated (Colquhoun et al., 1998a, 1998b; Goodfellow et al., 1990; Gürtler et al., 2004; Schuppler et al., 1995).

Improvements in the taxonomy of mycolic acid-containing actinomycetes has led to some species being reclassified and others becoming synonyms of previously described taxa. *Rhodococcus aichiensis* Tsukamura 1982a and *Rhodococcus chlorophenolicus* Apajalahti et al. 1986 have been reclassified as *Gordonia aichiensis* Klatte et al. 1994a and *Mycobacterium chlorophenolicum* Häggblom et al. 1994. In addition, *Rhodococcus chubuensis* Tsukamura 1982a, *Rhodococcus luteus* Nesterenko et al. 1982 and *Rhodococcus roseus* Tsukamura et al. 1991 have become synonyms of *Gordonia sputi* (Tsukamura 1978) Riegel et al. 1994, *Rhodococcus fascians* (Tilford 1936) Goodfellow 1984b, and *Rhodococcus rhodochrous* (Zopf 1891) Tsukamura 1974, respectively. In contrast, *Nocardia corynebacteroides* Serrano et al., 1972 and *Tsukamurella wratislaviensis* Goodfellow et al., 1995 have been reclassified as *Rhodococcus corynebacteroides* (Serrano et al., 1972) Yassin and Schaal 2005 and *Rhodococcus wratislaviensis* Goodfellow et al. 1995, 2002. Rainey et al., (1995b) confirmed that *Nocardia calcarea* Metcalfe and Brown 1957 should be seen as a synonym of *Rhodococcus erythropolis* (Gray and Thornton 1928) Goodfellow and Alderson 1977, and *Nocardia restricta* Turfitt 1944 as a synonym of *Rhodococcus equi* (Magnusson 1923) Goodfellow and Alderson 1977. It has also been shown that the well-known cholesterol oxidase-producing strain, *Brevibacterium sterolicum* ATCC 21387 (Fujishiro et al., 1990), is a strain of *Rhodococcus equi* (Ladrón et al., 2003).

The phylogenetic structure of the genus *Rhodococcus* is complex though several equidistant lineages have been recognized in the 16S rRNA gene tree (Goodfellow et al., 1998a; Goodfellow and Maldonado, 2006; Gürtler et al., 2004; Matsuyama et al., 2003; McMinn et al., 2000; Rainey et al., 1995a), notably those corresponding to the *Rhodococcus equi, Rhodococcus erythropolis*, and *Rhodococcus rhodochrous* subclades (Figure 96). It is particularly important to resolve the taxonomic status of *Rhodococcus equi* owing to its significance as a causal agent of bronchopneumonia in foals and its increasing role as a human pathogen. The results of 16S rRNA sequencing studies are equivocal in asmuch as the position of *Rhodococcus equi* within the evolutionary radiation occupied by the genera *Nocardia* and *Rhodococcus* is not stable. It is not clear, for instance, whether this taxon is more closely related to the genus *Nocardia* than to other members of the genus *Rhodococcus* (Goodfellow et al., 1998a; Matsuyama et al., 2003; Ruimy et al., 1994, 1995; Yoon et al., 2000a) or whether it merits recognition as a genus in its own right (Gürtler et al., 2004; McMinn et al., 2000; Rainey et al., 1995a). This situation is compounded by the fact that *Rhodococcus equi* is a heterogeneous species (Butler et al., 1987; Goodfellow et al., 1982a; Gotoh et al., 1991; McMinn et al., 2000; McNeil and Brown, 1994).

Differentiation of the species of the genus *Rhodococcus*

Rhodococcus species can be distinguished using a combination of 16S rRNA gene sequence (Figure 96) and DNA–DNA relatedness data (Table 42). It is difficult to assign unknown rhodococci to the *Rhodococcus equi, Rhodococcus erythropolis*, and *Rhodococcus rhodochrous* 16S rRNA clades using only phenotypic properties. In contrast, combinations of phenotypic features can be used to distinguish between species assigned to each of these taxa (Table 43, Table 44, and Table 45). There is evidence that differences in fatty acid profiles can be used for this purpose (Table 46, Table 47, and Table 48), and that rapid enzyme tests based on the fluorophores 7-amino-4-methylcoumarin and 4-methylumbelliferone provide a reliable means of distinguishing between some *Rhodococcus* species (Goodfellow et al., 1990), as does Curie-point pyrolysis mass spectrometry (PyMS; (McMinn et al., 2000). Curie-point PyMS also provides a rapid and effective way of dereplicating rhodococci for biotechnological purposes (Brandão et al., 2002; Colquhoun et al., 2000).

Prompt and accurate diagnosis of equine pneumonia due to *Rhodococcus equi* is necessary to foster improved clinical outcomes by early medical intervention given the insidious onset and development of the disease. Microbiological and serological methods have been recommended for this purpose (Giguere and Prescott, 1997; Takai et al., 1994) but they are not as rapid or sensitive as PCR assays (Sellon et al., 2001). Species-specific nonproprietary primers have been designed to detect a unique 700-bp fragment of *Rhodococcus equi* chromosomal DNA (Arriaga et al., 2002). Rapid identification of *Rhodococcus equi* can also be achieved by using a PCR assay that targets the *choE* gene (Ladrón et al., 2003). A study using a simple PCR typing system for *Rhodococcus equi* based on three virulent plasmids suggests that there is a clear association between specific plasmid types and animal hosts (Ocampo-Sosa et al., 2007).

List of species of the genus *Rhodococcus*

1. **Rhodococcus rhodochrous** (Zopf 1891) Tsukamura 1974, 43[AL] [*Staphylococcus rhodochrous* Zopf 1889, 173; *Rhodococcus rubropertinctus* (Hefferan 1904) Tsukamura 1974, 43]

rho.do.ch′rous. Gr. n. *rhodon* the rose; Gr. n. *khoria* color; N.L. masc. adj. *rhodochrous* rose colored

Gram-stain-positive actinomycete. Forms a primary mycelium that fragments into rods and cocci. Rough, orange to red colonies are formed on glucose-yeast extract agar, Sauton's agar, and egg media. Grows between 10 and 40°C. Hydrolyzes arbutin, reduces nitrate to nitrite, but does not produce hydrogen sulfide. Positive for catalase, 2-deoxythymidine-5′-*p*NP-phosphate, β-esterase and *p*NP-β-D-xyloside, but negative for allantoinase, α-esterase, β-galactosidase, nicotinamidase, *p*NP-phosphoryl-choline, oxidase, and pyrazinamidase. Degrades adenine, DNA, and uric acid, but not cellulose, chitin, elastin, Tweens 20, 40, or 60, or xylan. Acid is produced from dextrin, fructose, glucose, glycerol, maltose, mannose, but not from adonitol, amygdalin, D- or L-arabinose, dulcitol, ethanol, galactose, glycogen, inositol, inulin, lactose, mannitol, melezitose, raffinose, rhamnose, sorbitol, sucrose, trehalose, or xylose. Grows on D- and L-arabitol, biphenyl (weak), *iso*-butanol, 2,3-butylene glycol, glycerol, inulin, mannose, propylene glycol, toluene, xylitol, adipate, benzoate, caprate, *p*-cresol, fumarate, glutarate, 3- and 4-hydroxybenzoate, γ-hydroxybutyric acid, lactate, malate, octanoate, 2-oxyglutarate, phenylacetate, pimelate, propionate, sebacate, tartrate, testosterone, and quinate as sole carbon sources, but not on amygdalin, D- or L-arabinose, arbutin, dulcitol, glycogen, lactose, α-methyl-D-galactoside, raffinose, starch, turanose, D- or L-xylose, *N*-acetyl-D-glucosamine, γ-aminobutyrate, hippurate, 2-hydroxyvalerate, D-lactic acid methyl ester, malonate, monoethanolamine, phenol. L-Alanine, L-leucine, DL-norleucine, tyramine, L-tyrosine, and valine are used as sole nitrogen sources, but not L-aspartate, betaine, D-glucosamine, L-proline, putrescine, D- or L-serine, L-tryptophan or trimethylenediamine. Strains utilize dodecane, gaseous hydrocarbons, degrade polychlorobenzoates, oxidize propane, convert acetylene to acetaldehyde, ethanol, acetate, and carbon dioxide and are a source of muconic acid. Resistant to crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), picric acid (0.2%, w/v), sodium azide (0.01%, w/v), sodium chloride (7.0%, w/v), sodium nitrate (0.2%, w/v), and sodium salicylate (0.1%, w/v). Susceptible to 5-fluorouracil (5 µg per ml) and mitomycin (5 µg per ml), but not to ethambutol (5 µg per ml) or rifampin (25 µg per ml). Additional phenotypic features are shown in Table 45. Mycolic acids have 38–48 carbon atoms. The fatty acid profile is shown in Table 48. The major menaquinone is MK-8(H_2).

Source: soil.

DNA G+C content (mol%): 62–69 (T_m).

Type strain: ATCC 13808, ATCC 25592, CCUG 47165, CIP 104376, DSM 43241, HAMBI 1959, IEGM 62, NBRC 16069, JCM 3202, LMG 5365, NBRC 16069, NCTC 10210, NRRL B-2149, NRRL B-16536, VKM Ac-1227.

Sequence accession no. (5S rRNA): X55254.

Sequence accession no. (16S rRNA gene): X79288.

Sequence accession no. (gyrB): AB014173.

Additional remarks: Rhodococcus rhodochrous is used in the commercial production of acrylamide by the Nitto Chemistry Industry Company Ltd. in Japan.

2. **Rhodococcus aetherivorans** Goodfellow, Jones, Maldonado and Salanitro 2004, 64[AL]

a.e.the.ri.vo′rans. N.L. n. *aether aetheris* ether; L. part. adj. *vorans* eating, devouring; N.L. part. adj. *aetherivorans* devouring ether.

Gram-stain-positive, slightly acid–alcohol-fast actinomycete with a rod–coccus life cycle. Rough pinkish colonies are formed on modified Bennett's and peptone-yeast extract agars. Degrades methyl *t*-butyl ether, starch, but not DNA or uric acid. Reduces nitrate to nitrite, but does not hydrolyze esculin. Utilizes L-arabitol, *iso*-butanol, 2,3-butylene glycol, glycerol, inulin, mannose, xylitol, γ-aminobutyrate, benzoate, fumarate, γ-hydroxybutyric acid, and monoethanolamine as sole carbon sources, but not arbutin, dulcitol, methyl-α-D-glucoside, methyl-β-D-glucoside, or gluconate. L-Leucine is used as a sole nitrogen source. Additional phenotypic features are shown in Table 45. Mycolic acids co-migrate with those of the type strain of *Rhodococcus rhodochrous.* The major menaquinone is MK-8(H_2).

Source: enrichments of a petrochemical biotreater sludge obtained from a chemical effluent treatment plant.

DNA G+C content (mol%): not determined.

Type strain: 10bc312, DSM 44752, JCM 14343, NCIMB 13964.

Sequence accession no. (16S rRNA gene): AF447391.

3. **Rhodococcus baikonurensis** Li, Kawamura, Fujiwara, Naka, Liu, Huang, Kobayashi and Ezaki 2004c, 833[VP]

bai.ko.nur.en′sis. N.L. masc. adj. *baikonurensis* of or belonging to Baikonur, the town in Kazakhstan where the Mir space station was launched.

Gram-stain-positive actinomycete forms branched filaments which fragment into rods and cocci. Colonies are smooth, opaque and slightly pink on brain heart infusion agar. Degrades Tween 40, but not adenine, or arbutin. Resistant to lysozyme. Acid is not produced from D- or L-arabinose. Grows on 2,3-butylene glycol (weak), mannose (weak), acetate, L-glutamic acid, L-glutamic acid (weak), α-, β-, and γ-hydroxybutyric acid, α-ketovaleric acid, lactic acid, D-lactic acid methyl ester (weak), L-malic acid, methyl pyruvate, monomethyl succinate, propionic acid (weak), pyruvic acid, succinic acid (weak), and succinamic acid (weak), but not on arbutin, catechol, β-dextrin, lactulose, maltotriose, 3-methyl-glucose, methyl-α-D-glucoside, methyl-β-D-glucoside, palatinose, salicin, turanose, or xylitol. Alaninamide (weak), L-asparagine and putrescine are used as sole nitrogen sources, but not L-alanyl-glycine, carbendazim, uridine, or uridine 5′-monophosphate. Additional phenotypic features are shown in Table 44. A1γ cell-wall peptidoglycan. Mycolic acids have 46–54 carbon atoms. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is cardiolipin, phosphatidylethanolamine, phosphatidylinositol, and

phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: air in the Russian space laboratory Mir.

DNA G+C content (mol%): 56 (T_m).

Type strain: A1-22, DSM 44587, GTC 1041, JCM 11411, NBRC 100611.

Sequence accession no. (16S rRNA gene): AB071951.

4. **Rhodococcus coprophilus** Rowbotham and Cross 1979, 80[VP] (Effective publication: Rowbotham and Cross 1977b, 136.)

co.pro.phi′lus. Gr. n. *kopros* dung; Gr. adj. *philos* loving; N.L. masc. adj. *coprophilus* dung loving.

Gram-stain-positive, non-acid-fast actinomycete. Forms a well-developed primary mycelium that fragments into rods and cocci after incubation for several days. Aerial hyphae are produced and may be branched. Rhizoid colonies (2 mm in diameter) with a central orange papilla are formed on Bennett's agar. Pigmentation is enhanced by light. Positive for catalase and nicotinamidase, but negative for acetamidase, acid phosphatase, 2-deoxythymidine-5′-*p*NP-phosphate, α- and β-esterase, oxidase, *p*NP-phosphorylcholine and *p*NP-β-D-xyloside. Degrades uric acid, but not adenine, casein, cellulose, chitin, elastin, guanine, hypoxanthine, xanthine, or xylan. Reduces nitrate to nitrite. Produces hydrogen sulfide, but does not hydrolyze arbutin. Acid is not produced from L-arabinose, galactose, inulin, lactose, raffinose, or rhamnose. Assimilates L-arabitol, arbutin, *iso*-butanol, cetyl alcohol, mannose, α-methyl-D-galactoside, raffinose, toluene (weak), xylitol, acetate, adipate, benzoate, isobutyrate, *p*-cresol, fumarate, 3-hydroxybenzoate, γ-hydroxybutyric acid, lactic acid, 2-oxyglutarate, pimelate, propionate, sebacate, testosterone, and valerate as sole carbon sources, but not L-arabinose, D-arabitol, biphenyl, butane-1,3-diol, butane-1,4-diol, dulcitol, glycerol, inulin, lactose, starch, turanose, D- or L-xylose, *N*-acetyl-D-glucosamine, γ-aminobutyrate, caprate, glutarate, glycollate, 4-hydroxybenzoate, 2-hydroxyvalerate, malate, D-mandelic acid, monoethanolamine, phenol, phenylacetate, tartrate, or quinate. L-Leucine is used as a sole nitrogen source, but not D- or L-alanine, L-asparagine, L-aspartate, D-glucosamine, L-glycine, DL-norleucine, L-phenylalanine, L-proline, putrescine, D- or L-serine, trimethylenediamine, tyramine, L-tyrosine, or valine. Grows in the presence of crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), sodium azide (0.02%, w/v), and sodium chloride (7.0%, w/v), but is sensitive to lysozyme. Resistant (μg per ml) to capreomycin (100), cephaloridine (100), doxycycline 9100), erythromycin (50), fusidic acid (100), gentamicin (10), lincomycin (100), minocycline (50), neomycin (50), oleandomycin (50), polymyxin B (100), rifampin (50), streptomycin (100), tobramycin (50), and vancomycin (50). Additional phenotypic features are shown in Table 45. Mycolic acids have 38–48 carbon atoms. The fatty acid profile is shown in Table 48.

Source: dung of cows, sheep, goats, horses, and donkeys. It is common on grass and in the soil beneath grazed pastures, and is washed into streams and lakes where it can accumulate in the sediment.

DNA G+C content (mol%): 69–64 (T_m).

Type strain: CUB 687, ATCC 29080, CIP 104178, DSM 43347, IEGM 600, JCM 3200, LMG 5357, NBRC 100603, NCIMB 11211, NCTC 10994, NRRL B-16537, VKM Ac-571.

Sequence accession no. (16S rRNA gene): X80626.

Sequence accession no. (gyrB): AB014271.

5. **Rhodococcus corynebacterioides** (Serrano, Tablante, de Serrano, de San Blas and Imaeda 1972) Yassin and Schaal 2005, 1347[VP] (Basonym: *Nocardia corynebacterioides* Serrano, Tablante, de Serrano, de San Blas and Imaeda 1972, 347.)

co.ry.ne.bac.te.ri.oi′des. N.L. neut. n. *Corynebacterium* bacterial genus name; Gr. suff. *-oides* similar to; N.L. fem. adj. *corynebacterioides* similar to *Corynebacterium*.

Gram-stain-positive, partially acid–alcohol-fast actinomycete. Forms short rods, V-forms, clumps, and coccoid elements, and smooth, orange-red pigmented colonies. Grows at 22–45°C. Degrades adenine, but not casein, elastin, gelatin, guanine, xanthine, or xylan. Nitrate is not reduced to nitrite. Does not produce hydrogen sulfide or hydrolyze hippurate. Acid is produced from mannose and salicin, but not from adonitol, arabinose, dulcitol, inulin, lactose, or melibiose. Acetate, 2,3-butylene glycol, propylene glycol, malate, D- and L-xylose (weak), and testosterone are used as sole carbon sources, but not adipic acid, adonitol, *iso*-amylalcohol, L-arabinose, erythritol, lactose, raffinose, or lactic acid. L-Phenylalanine (weak), L-proline, D- and L-serine and ornithine are used as sole nitrogen sources, but not L-alanine, L-arginine, gelatin, L-histidine, methionine, or potassium nitrate. Resistant to sodium azide (0.01%, w/v) (weak), but susceptible to sodium chloride (10.0%, w/v), chloramphenicol (10 μg per ml), cephalothin (25 μg per ml), dihydrostreptomycin (2 μg per ml), novobiocin (30 μg per ml), and polymyxin (300 μg per ml). Additional phenotypic features are shown in Table 45. Fatty acid profile shown in Table 48. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: air contaminated culture media.

DNA G+C content (mol%): not determined.

Type strain: DSM 20151, ATCC 14898, CCUG 37877, CIP 104510, JCM 3376, JCM 3391, NBRC 14404, NRRL B-24037.

Sequence accession no. (16S rRNA gene): AF430066.

Sequence accession no. (gyrB): AB014109.

Additional remarks: in ultrathin sections the cell wall is composed of an outermost diffuse layer and a moderately dense layer 10 μm thick. The total thickness of the cell wall is about 18–20 μm.

6. **Rhodococcus equi** (Magnusson 1923) Goodfellow and Alderson 1977, 116[AL] [*Corynebacterium equi* Magnusson 1923, 36; *Corynebacterium hoagii* (*sic*) (Morse) Eberson 1918, 11; *Nocardia restricta* (Turfitt) McClung 1974, 743.]

e′qui. L. n. *equus* horse; L. gen. n. *equi* of the horse.

Rod–coccus life cycle though traces of elementary branching may be observed at early stages of growth. Smooth, shiny, orange to red colonies with entire margins are formed on glucose-yeast extract agar. Some strains

produce abundant slime which may drop onto the cover of inverted Petri dishes during incubation. Grows at 10–40°C. Positive for 2-deoxythymidine-5′-*p*NP-phosphate, *p*NP-phosphorylcholine, phosphoamidase and urease, but negative for acetamidase, allantoinase, nicotinamidase, and *p*NP-β-D-xyloside. Does not degrade arbutin, cellulose, chitin, Tweens 20, 40, or 60. Does not produce acid from L-arabinose, inositol, mannitol, rhamnose, or sorbitol. Amyl alcohol, butane-1,3-diol, butan-1-ol, ethanol, glycerol, propane 1, 2-diol, propan-1-ol, propylene glycol, caprate, fumarate, glutarate, 3- and 4-hydroxybenzoate, *m*- and *p*-hydroxybenzoic acid, 2-hydroxyvalerate, octanoate, 2-oxyglutarate, phenylacetate, pyruvate, and testosterone are used as sole carbon sources, but not adonitol, D-arabitol, butane-1,4-diol, 2,3-butylene glycol, cellobiose, erythritol, galactose, glycogen, inulin, melezitose, propan-2-ol, salicin, turanose, D-xylose, adipate, *N*-acetyl-D-glucosamine, γ-aminobutyrate, *p*-cresol, gluconate, hippurate, malonate, mucate, phenylacetate, pimelate, sebacate, or quinate. Acetamide, L-aspartate, D-glucosamine, L-leucine, and L-tyrosine are used as sole nitrogen sources, but not L-alanine, L-proline, putrescine, D- or L-serine, ornithine, trimethylenediamine, tyramine, or valine. Grows in the presence of crystal violet (0.001%, w/v), phenyl ethanol (0.3%, v/v), picric acid (0.2%, w/v), and sodium azide (0.02%, w/v). Susceptible to lysozyme, phenol (0.1, w/v), 5-fluorouracil (5 µg per ml) and mitomycin (5 µg per ml), but resistant (µg per ml) to ampicillin (20), erythromycin (4), gentamicin (8), lincomycin (64), minocycline (0.125), neomycin (8), novobiocin (4), polymyxin (256), rifampin (0.25), streptomycin (5), sulfadiazine (100), tetracycline (50), and tobramycin (10). Additional phenotypic features are shown in Table 43. Mycolic acids have 30–38 carbon atoms. The fatty acid profile is shown in Table 46. Causes bronchopneumonia in foals; occasionally infects other domestic animals such as cattle and pigs, and causes infections in human patients, notably ones compromised by immunosuppressive drug therapy, AIDS, or lymphoma.

Source: soil, herbwire dung, and the intestinal tract of cows, horses, pigs and sheep.

DNA G+C content (mol%): 58.5 (T_m).

Type strain: ATCC 25729, ATCC 6939, CCUG 892, CIP 54.72, DSM 20307, HAMBI 2061, NBRC 14956, JCM 1311, JCM 3209, LMG 18452, NBRC 101255, NCTC 1621, NRRL B-16538, VKM Ac-953.

Sequence accession no. (16S rRNA gene): X80614.

Sequence accession no. (gyrB): AB014110.

Taxonomic note: on the Approved Lists of Bacterial Names, this nomenclatural name is incorrectly cited as *Rhodococcus equi* (Magnusson 1923) Goodfellow and Alderson 1979 (*sic*). This has subsequently been corrected by Euzéby (1997).

7. **Rhodococcus erythropolis** (Gray and Thornton 1928) Goodfellow and Alderson 1979, 80[VP] (Effective publication: Goodfellow and Alderson 1977, 115; *Mycobacterium erythropolis* Gray and Thornton 1928, 87; *Nocardia calcarea* Metcalfe and Brown 1957, 568.)

e.ry.thro′po.lis. Gr. adj. *eruthros* red; Gr. n. *polis* a city. N.L. n. *erythropolis* red city.

Cocci give rise to branched filaments which fragment into cocci. Rough, orange to red colonies are formed on glucose-yeast extract and Sauton's agars. Grows at 4–40°C. Positive for 2-deoxythymidine-5′-*p*NP-phosphate, *p*NP-phosphorylcholine, *p*NP-β-D-xyloside, and phosphatase, but negative for allantoinase and oxidase. Degrades adenine, arbutin, and L-tyrosine, but not casein, cellulose, chitin, elastin, hypoxanthine, starch, Tweens 20, 40, or 60, or xylan. Acid is produced from glucose, glycerol, sorbitol, sucrose, and trehalose, but not from adonitol, D- and L-arabinose, cellobiose, galactose, glycogen, inulin, melezitose, rhamnose, or xylose. Grows on butane-1,3-diol, cetyl alcohol, ethanol, propylene glycol, salicin, adipate, acetate, *N*-acetyl-D-glucosamine, γ-aminobutyrate, caprate, citrate, *p*-cresol, fumarate, gluconate, glutarate, 4-hydroxybenzoate, *p*-hydroxybenzoic acid, α-hydroxybutyrate (weak), γ-hydroxybutyrate, 2-hydroxyvalerate, lactate, malate, methyl pyruvate, 2-oxyglutarate, phenylacetate, pimelate, propionate, pyruvate, sebacate, stearate, succinate, testosterone and quinate as sole carbon sources, but not amygdalin, D-arabitol, butane-1,4-diol, catechol, dextran, β-dextrin, dulcitol, glycogen, turanose, xylitol, benzoate, 3-hydroxybenzoate, *m*-hydroxybenzoate, β-hydroxybutyrate, malonate, or tartrate. Acetamide, D- and L-alanine, L-asparagine, D-glucosamine, L-leucine, DL-norleucine, L-phenylalanine, L-proline, putrescine, L-serine, and valine are used as sole nitrogen sources, but not L-alanine-glycine, L-aspartate, benomyl, carbendazim, 2,4-dinitrophenol, L-glycine, D-serine, trimethylenediamine, tyramine, or L-tyrosine. Resistant to crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), sodium azide (0.02%, w/v), sodium chloride (7.0%, w/v), but susceptible to lysozyme. Additional phenotypic features are shown in Table 44. Mycolic acids have 36–48 carbon atoms. The fatty acid profile is shown in Table 47. The major menaquinone is MK-8(H_2).

Source: soil.

DNA G+C content (mol%): 61–67 (T_m).

Type strain: ATCC 4277, CIP 104179, DSM 43066, HAMBI 1953, IEGM 7, JCM 3201, JCM 20419, LMG 5359, NBRC 15567, NCIMB 9158, NCTC 13021, NRRL B-16025, VKM Ac-858).

Sequence accession no. (16S rRNA gene): X81929.

Sequence accession no. (5S rRNA): X05057.

Sequence accession no. (gyrB): AB014112.

Additional remarks: strains hydrolyze halogenated compounds, such as 1-chlorobutane, 1-chloropentane, 1-chlorohexane, 1-bromobutane, and 1-bromohexane in either aqueous or solid phase, produce *sec*-alcohol dehydrogenase by reducing ketones, can remove organic sulfur from fossil fuels and dibenzothiophenes, and degrades chloroaromatics and polychlorobiphenyls.

8. **Rhodococcus fascians** (Tilford 1936) Goodfellow 1984a, 503[VP] [Effective publication Goodfellow 1984b, 227; *Phytomonas fascians* Tilford 1936, 394; *Corynebacterium fascians* (Tilford) Dowson 1942, 313.]

fas′ci.ans. L. part. adj. *fascians* binding together, bundling.

Branched hyphae fragment into rods and cocci. Entire, convex, orange colonies formed on glucose-yeast extract agar. Thiamine is required for growth. Grows at 10–40°C. Positive for acid phosphatase, allantoinase, naphthol-AS-BI-phosphohydrolase, pyrazinamidase, urease, and valine

arylamidase, but negative for *N*-acetyl-β-glucosamine, cystine arylamidase, 2-deoxythymidine-5′-*p*NP-phosphate, esterase (C8), α- and β-galactosidase, β-glucosidase, β-glucuronidase, oxidase, *p*NP-phosphoryl-choline, and *p*NP-β-D-xyloside. Degrades adenine and L-tyrosine, but not arbutin, casein, cellulose, chitin, elastin, starch, or xylan. Acid is produced from dextrin, ethanol, fructose, galactose, glucose, glycerol, mannitol, mannose, ribose, sorbitol, sucrose, and trehalose, but not from adonitol, amygdalin, D- or L-arabinose, arbutin, cellobiose, dulcitol, glycogen, inositol, inulin, lactose, methyl-α-D-glucoside, methyl-β-D-glucoside, raffinose, rhamnose, salicin, or xylose. Assimilates D-arabitol, ethanol, xylitol, *N*-acetyl-D-glucosamine, citrate, *p*-cresol, fumarate, gluconate, glutarate, 4-hydroxybenzoate, *m*- or *p*-hydroxybenzoate acid, 2-hydroxyvalerate, lactate, malate, 2-oxyglutarate, pyruvate, sebacate, succinate, and quinate as carbon sources, but not adonitol, dulcitol, turanose, adipate, acetate, γ-aminobutyrate, benzoate, caprate, hippurate, 3-hydroxybenzoate, malonate, phenylacetate, pimelate, or testosterone. D- and L-Alanine, benomyl, D-glucosamine, L-proline, putrescine, D-serine, L-tyrosine, and valine are used as sole nitrogen sources, but not acetamide, L-aspartate, betaine, 2,4-dinitrophenol, L-leucine, DL-norleucine, L-serine, L-threonine, trimethylenediamine, or tyramine. Grows in the presence of crystal violet (0.0001%, w/v), phenol (0.1%, w/v), but is susceptible to lysozyme, phenyl ethanol (0.3%, v/v), sodium azide (0.01%, w/v), and sodium chloride (5.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 38–52 carbon atoms. The fatty acid profile is shown in Table 47.

Source: Chrysanthemum morifolium.

Type strain: ATCC 12974, CFBP 2401, CIP 104713, DSM 20669, ICMP 5833, NBRC 12155, JCM 10002, LMG 3623, NCPPB 3067, NRRL B-16937, VKM Ac-1462.

Sequence accession no. (16S rRNA gene): X79186.

Sequence accession no. (gyrB): AB075563.

9. **Rhodococcus globerulus** Goodfellow, Weaver and Minnikin 1985, 224[VP] [Effective publication: Goodfellow, Weaver and Minnikin 1982c, 741; *Mycobacterium globerulum* Gray 1928, 265; *Nocardia globerula* (*sic*) (Gray 1928) Waksman and Henrici 1948, 903; *Nocardia corynebacterioides* (*sic*) Serrano, Tablante, Serrano, San Blas and Imaeda 1972, 348.]

glo.be′ru.lus. N.L. dim. masc. adj. *globerulus* globular.

Cocci give rise to branched filaments which fragment into rods and cocci. Entire, rough, pink to red colonies are formed on glucose-yeast extract agar. Positive for allantoinase, 2-deoxythymidine-5′-*p*NP-phosphate, *p*NP-phosphorylcholine and *p*NP-β-D-xyloside, but negative for benzamidase and oxidase. Arbutin is degraded, but not adenine, casein, cellulose, chitin, elastin, starch, L-tyrosine, or xylan. Acid is produced from dextrin, ethanol, fructose, glucose, glycerol, maltose, mannitol, mannose, sorbitol, sucrose, and trehalose, but not from adonitol, amygdalin, D- or L-arabinose, cellobiose, dulcitol, galactose, glycogen, inositol, lactose, melezitose, raffinose, rhamnose, or xylose. Grows on D-arabitol, β-dextrin (weak), ethanol, propylene glycol, xylitol, adipate, acetate, γ-aminobutyrate, benzoate, caprate, citrate, fumarate, gluconate, 3- and 4-hydroxybenzoate, *p*-hydroxybenzoate, γ-hydroxybutyrate acid, lactate, malate, methyl pyruvate, pimelate, pyruvate, sebacate, succinate and quinate as sole carbon sources, but not adonitol, 2,3-butylene glycol, catechol, dulcitol, lactose, salicin, turanose, *N*-acetyl-D-glucosamine, *p*-cresol, glutarate, hippurate, *m*-hydroxybenzoate, α- or β-hydroxybutyrate, 2-hydroxyvalerate, malonate, octanoate, 2-oxyglutarate, phenylacetate, or testosterone. Acetamide, D- or L-alanine, L-leucine, putrescine, D-serine and valine are used as sole nitrogen sources, but not L-alanyl-glycine, L-asparagine, L-aspartate, benomyl, betaine, carbendazim, 2,4-dinitrophenol, D-glucosamine, DL-norleucine, L-proline, L-serine, L-ornithine, L-threonine, L-tryptophan, trimethylenediamine, tyramine, or L-tyrosine. Resistant to crystal violet (0.001%, w/v), phenol (0.001%, w/v), phenyl ethanol (0.3%, v/v), sodium azide (0.02%, w/v), sodium chloride (7.0%, w/v), 5-fluorouracil (20 μg per ml), and mitomycin C (5 μg per ml), but susceptible to lysozyme. Additional phenotypic features are shown in Table 44. Mycolic acids have 30–42 carbon atoms. The fatty acid profile is shown in Table 47.

Source: soil.

DNA G+C content (mol%): 63–67 (T_m).

Type strain: R58, ATCC 25714, CIP 104174, DSM 43954, IEGM 591, NBRC 14531, JCM 7472, NRRL B-16938.

Sequence accession no. (16S rRNA gene): X80619.

Sequence accession no. (gyrB): AB014114.

10. **Rhodococcus gordoniae** Jones, Brown, Mishra, Perry, Steigerwalt and Goodfellow 2004, 409[VP]

gor.don.i′a.e. N.L. gen. fem. n. *gordoniae* of Gordon, named after Ruth Gordon, a celebrated microbial systematist.

Acid-fast actinomycete. Forms branched filaments that fragment into rod–coccus elements. Colonies are slightly raised, shiny and pigmented pink to coral with filamentous edges on blood and chocolate agar. Degrades DNA, but not casein, hypoxanthine, uric acid, or xanthine. Nitrate is reduced to nitrite. Degrades phenol at high concentrations (>25 mM). Acid is produced from L-arabinose, fructose, galactose, glucose, glycerol, mannitol, mannose, salicin, sorbitol, sucrose, trehalose, and xylose, but not from inositol, maltose, or rhamnose. Grows on L-arabitol, arbutin, mannose, xylitol, γ-aminobutyrate, benzoate, fumarate, γ-hydroxybutyrate, and monoethanolamine as sole carbon sources, but not dulcitol, glycerol, α-methyl-D-galactoside, or methyl-α-D-glucoside. Acetamide and L-leucine are used as sole nitrogen sources. Resistant to lysozyme, clindamycin, and norfloxacin, but susceptible to amikacin, amoxicillin/clavulinate, ampicillin, ampicillin/sulbactam, cefotaxime, cephalothin, ciprofloxacin, doxycycline, erythromycin, gentamicin, imipenem, minocycline, oxacillin, penicillin, rifampin, sulfamethoxazole, tetracycline, trimethoprim/sulfamethoxazole, and vancomycin. Additional phenotypic features are shown in Table 45. Mycolic acids co-migrate with those of *Rhodococcus rhodochrous.* The major menaquinone is MK-8(H_2).

Source: a blood culture of an immunoincompetent patient with fatal pneumonia associated with adult respiratory disease syndrome.

DNA G+C content (mol%): not determined.

Type strain: W 4937, DSM 44689, JCM 12658, NCTC 13296.

Sequence accession no. (16S rRNA gene): AY233201.

11. **Rhodococcus imtechensis** Ghosh, Paul, Prakash, Mayilraj and Jain 2006, 1968[VP]

im.tech.en′sis. N.L. masc. adj. *imtechensis* of or pertaining to the Institute of Microbial Technology (IMTECH), Chandigarh, India, where the type strain was characterized.

Gram-stain-positive actinomycete with a hyphal-rod–coccus life cycle. Circular, glistening, opaque, convex and creamish-pink colonies with smooth margins are produced on tryptic soy agar. Grows at 10–37°C and pH 5.0–10.0. Catalase-positive. Oxidase-negative. Does not produce hydrogen sulfide, or reduce nitrate. Degrades *p*-nitrophenol and 2,4-dinitrophenol, but not arbutin, casein, elastin, gelatin, or starch. Acid is produced from fructose, galactose, glucose, inositol, lactose, maltose, mannitol, raffinose, sorbitol, and sucrose, but not from adonitol, cellobiose, or dulcitol. α-Cyclodextrin, L-fucose, D-galacturonic acid, lactulose, methyl-α-D-mannoside, D-psicose, acetate, D-lactic acid methyl ester, propionate, and pyruvate are used as sole carbon sources, but not amygdalin, 2,3-butylene glycol, β-dextrin, D-fructose-6-phosphate, gentiobiose, α-D-glucose-1-phosphate, glycogen, inosine, mannan, methyl-β-D-galactoside, salicin, stachyose, *N*-acetyl-D-glucosamine, D-glucuronic acid, or malate. 2,4-Dinitrophenol, *p*-nitrophenol, L-proline, L-pyroglutamic acid, L-serine, and valine are used as sole nitrogen sources, but not adenosine-5′-monophosphate, 2′-deoxyadenosine, putrescine, thymidine, thymidine-5′-monophosphate, or uridine. Resistant to (µg per ml) ampicillin (10) and cephaloridin (30), but sensitive to chloramphenicol (10), chlortetracycline (30), gentamicin (10), neomycin (30), norfloxacin (10), oleandomycin (15), rifampin (5), streptomycin (10), tetracycline (30), tobramycin (10), and vancomycin (30). Additional phenotypic features are shown in Table 44. Mycolic acids are present. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, and traces of diphosphatidylglycerol. The major menaquinone is MK-8(H_2); MK-9(H_2) is present in trace amounts.

Source: pesticide-contaminated site in Punjab State, India.

DNA G+C content (mol%): 72 (T_m).

Type strain: RKJ300, JCM 13270, MTCC 7085.

Sequence accession no. (16S rRNA gene): AY525785.

12. **Rhodococcus jostii** Takeuchi, Hatano, Sedlácek and Pácová 2002, 413[VP]

jos′ti.i. N.L. gen. masc. n. *jostii* of Jošt, in honor of Margrave Jošt Lucemburský (1351–1411), an important Czech ruler, from whose skeletal remains the strain was isolated.

Substrate mycelium fragments into rods or coccoid elements, which penetrate the agar. Form filaments (0.4–0.6 × 8–12 µm) in early growth phase and mostly cocci or short rods (0.2–0.5 × 1.7–3 µm) during the exponential growth phase. Colonies are light pink, opaque, convex with slightly irregular edges on peptone-yeast extract agar. Grows at 15–30°C, but not at 37°C. Positive for *N*-acetyl-β-glucosaminidase, catalase, β-galactosidase, and β-glucosidase, but negative for alkaline phosphatase, α-glucosidase, β-glucuronidase, lecithinase, pyrazinamidase, and pyrrolindonyl arylamidase. Does not reduce nitrate to nitrite. Degrades L-tyrosine, but not casein, DNA, gelatin, or starch. Acid is produced from fructose, glucose, lactose, mannitol, and xylose, but not from maltose. *N*-acetyl-D-glucosamine, fumarate, gluconate (weak), *m*- and *p*-hydroxybenzoic acid, succinate, tartrate (weak), and quinate are used as sole carbon sources, but not ethanol, citrate, lactate, or malate. Valine (weak) is used as a sole nitrogen source, but not L-leucine, L-proline, or L-serine. Additional phenotypic features are shown in Table 44. Mycolic acids are present. The fatty acid profile is shown in Table 47. The predominant menaquinone is MK-8(H_2).

Source: skeletal remains of Margrave Jošt Lucemburský, one of the most important Czech rulers.

DNA G+C content (mol%): 67.4 (HPLC).

Type strain: NBRC 16295, CCM 4760, JCM 11615.

Sequence accession no. (16S rRNA gene): AB046357.

Sequence accession no. (gyrB): AB088664.

13. **Rhodococcus koreensis** Yoon, Cho, Kang, Kim, Lee and Park 2000a, 1199[VP]

ko.re.en′sis. N.L. masc. adj. *koreensis* of or belonging to Korea, the country where the strain was isolated.

Gram-stain-positive actinomycete which shows elementary branching at early growth phase and cocci and rod-like elements in stationary phase. Cream colored, opaque, convex colonies with irregular edges are formed on tryptic soy agar. Grows at 25–30°C and pH 7.0–7.8. Catalase-positive. Oxidase-negative. Degrades 2,3-dinitrophenol, L-tyrosine, and uric acid, but not adenine, arbutin, casein, elastin, or starch.

Amygdalin, D-arabinose (weak), 2,3-butylene glycol, L-fucose, gentiobiose, D-galacturonic acid (weak), turanose, xylitol, acetate, citrate, malate, propionate, and succinate are used as sole carbon sources, but not adonitol, benzoate, α-cyclodextrin, dulcitol, lactulose, methyl-β-D-galactoside, methyl-α-D-mannoside, D-psicose, salicin, stachyose, *p*-hydroxybenzoic acid, or D-lactic acid methyl ester. 2,4-Dinitrophenol, *p*-nitrophenol, L-proline, L-serine, and uridine-5′-monophosphate (weak) are used as sole nitrogen sources, but not putrescine, or L-pyroglutamic acid. Resistant to sodium chloride (5.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 43–53 carbon atoms. The fatty acid profile is shown in Table 47. The predominant menaquinone is MK-8(H_2).

Source: industrial wastewater in Cheong-Ju.

DNA G+C content (mol%): 66 (HPLC).

Type strain: DNP505, CIP 106721, DSM 44498, JCM 10743, KCTC 0569BP, NBRC 100607.

Sequence accession no. (16S rRNA gene): AF124342, AF124343.

Sequence accession no. (gyrB): AB075566.

Additional remarks: 16S rRNA genes differ by 10 nucleotides (0.7% nucleotide sequence dissimilarity).

14. **Rhodococcus kroppenstedtii** Mayilraj, Krishnamurthi, Saha and Saini 2006, 981[VP]

krop.pen.sted′ti.i. N.L. gen. masc. n. *kroppenstedtii* of Kroppenstedt, to honor of Reiner Michael Kroppenstedt, a German microbiologist, for his many contributions to the taxonomy of actinomycetes.

Gram-stain-positive acid-fast actinomycete which forms rods and cocci that occur in groups. Colonies are small, smooth, glistening and convex with an orange-red pigmentation on tryptic soy agar. Grows well at 10–37°C, but not at 42°C. Grows at pH 5.0–11.0. Degrades adenine, Tweens 20, 40, and 60, but not elastin, gelatin, or guanine. Reduces nitrate to nitrite. Acid is produced from glucose, inositol, lactose, mannitol, raffinose, rhamnose and xylose, but not from adonitol, L-arabinose, cellobiose, dulcitol, fructose, galactose, inulin, maltose, mannose, melibiose, salicin, sucrose, or trehalose. Grows on lactic acid as a sole carbon source. L-Arginine, L-histidine, L-methionine, L-phenylalanine, potassium nitrate, L-proline, and D- and L-serine are used as sole nitrogen sources. Resistant to crystal violet (0.0001%, w/v), sodium azide (0.01%, w/v), sodium chloride (10.0%, w/v), and polymyxin (300 µg per ml). Additional phenotypic features are shown in Table 45. Mycolic acids have 42–50 carbon atoms and 1–3 double bonds. The fatty acid profile is shown in Table 48. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: a cold desert of the Himalayas, India.

DNA G+C content (mol%): 69.7 (HPLC).

Type strain: K07-23, DSM 44908, JCM 13011, NBRC 103113, MTCC 6634.

Sequence accession no. (16S rRNA gene): AY726605.

15. **Rhodococcus kunmingensis** Wang, Wang, Zhang, Xu, Jiang and Li 2008, 1469[VP]

kun.ming.en′sis. N.L. masc. adj. *kunmingensis* of or pertaining to Kunming, a city in Yunnan, south-west China.

Gram-stain-positive, acid-fast, actinomycete. Forms elementary branching filaments in early growth phase and coccoid-like elements at stationary phase. Circular, convex, smooth pink colonies are formed on yeast extract-malt extract agar. Grows at 10–37°C and pH 7.0–7.5.

Positive for *N*-acetyl-β-glucosamidase, catalase, esterase lipase (C8), fucosidase, α- and β-glucosidase, lipase C14, and naphthol-AS-BI-phosphohydrolase, but negative for cystine arylamidase, β-galactosidase, oxidase, and trypsin. Degrades L-arginine, L-asparagine, gelatin, L-histidine, and L-proline, but not starch. Reduces nitrate to nitrite, but does not produce hydrogen sulfide. Grows on amygdalin, butanediol, glucose, melibiose and xylitol as sole carbon sources, but not on chitin. Resistant to (µg per ml) clindamycin (2), norfloxacin (10), and trimethoprim (1.25), but susceptible to amikacin (30), amoxicillin/clavulinate, ampicillin (10), ciprofloxacin (5), erythromycin (15), gentamicin (10), rifampin (5), tobramycin (10), and vancomycin (30). Additional phenotypic features are shown in Table 43. Mycolic acids co-migrate with those of the type strain of *Rhodococcus equi*.The fatty acid pattern is shown in Table 46. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: a rhizosphere soil sample in Kunming, South-West China.

DNA G+C content (mol%): 64.9 (HPLC).

Type strain: YIM 45607, JCM 15626, KCTC 19149, DSM 45001.

Sequence accession no. (16S rRNA gene): DQ997045.

16. **Rhodococcus kyotonensis** Li, Furihata, Ding and Yokota 2007, 1957[VP]

kyo.to.nen′sis. N.L. masc. adj. *kyotonensis* of or pertaining to Kyoto, the source of soil from which the organism was isolated.

Gram-stain-positive, acid-fast actinomycete. Forms non-branching hyphae that fragment into short rod-to-coccus elements. Colonies are yellow-orange on tryptic soy agar. Grows at 27–30°C, but not at 40°C. Grows at pH 6.0–8.0. Positive for acid phosphatase, catalase, cystine arylamidase, esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, tryptophan deaminase, and valine, but negative for *N*-acetyl-β-glucosamidase, alkaline phosphatase, chymotrypsin, esterase lipase (C4), fucosidase, α- and β-galactosidase, β-glucosidase, β-glucuronidase, lipase, L-methionine-7-amino-methylcoumarin, *o*-nitro-phenyl-β-D-galactoside (ONPG)-arginine dihydrolase, ONPG-lysine decarboxylase, ONPG-ornithine decarboxylase, oxidase, and trypsin. Does not reduce nitrate or produce hydrogen sulfide. Degrades Tweens 20, 40, and 60, but not gelatin. D-Arabitol, sorbose, xylitol, and gluconate are used as sole carbon sources, but not adonitol, amygdalin, D-arabinose, arbutin, dulcitol, erythritol, D- or L-fucose, gentiobiose, glycogen, lyxose, methyl-α-D-glucoside, methyl-α-D-mannoside, methyl-β-D-xyloside, salicin, starch, tagatose, turanose, *N*-acetyl-D-glucosamine, citrate, 2-keto-gluconate, or 5-keto-gluconate. Grows in the presence of sodium chloride (9.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids co-migrate with those of the type strain of *Rhodococcus rhodochrous*.The fatty acid profile is shown in Table 47. The major menaquinone is MK-8(H_2); MK-7(H_2) and MK-9(H_2) are present in minor amounts.

Source: a soil sample in Kyoto City, Japan.

DNA G+C content (mol%): 64.5 (HPLC).

Type strain: DS472, CCTCC AB206088, IAM 15415, JCM 23211.

Sequence accession no. (16S rRNA gene): AB269261.

17. **Rhodococcus maanshanensis** Zhang, Zhang, Xiao, Liu and Goodfellow 2002, 2124[VP]

ma.an.shan.en′sis. N.L. masc. adj. *maanshanensis* of or belonging to Maanshan, the source of the soil from which the organism was isolated.

Gram-stain-positive, non-acid-fast actinomycete. Forms a branched substrate mycelium that fragments into rod- and coccoid-like elements. Cream colored, convex colonies with irregular edges are formed on Bennett's and tryptic soy agars. Grows well at 25–30°C and pH 6.0–8.5. Catalase-positive.

Hydrolyzes arbutin and reduces nitrate to nitrite. Oxidase-negative. Degrades adenine, Tweens 20 and 60, but not casein, elastin, guanine, hypoxanthine, starch, L-tyrosine, uric acid, or xanthine. Acid is produced from fructose, glucose, glycerol, mannose (weak), and ribose (weak), but not from L-arabinose, cellobiose, galactose, inulin, lactose, maltose, mannitol, raffinose, rhamnose, starch, sucrose, trehalose, or xylose. Salicin, turanose, acetate, fumarate, propionate, and succinate are used as sole carbon sources, but not adonitol, D-arabinose, dulcitol, erythritol, L-fucose, starch, xylitol, benzoate, citrate, formate, hippurate, phenol, tartrate, or 2,4,6-trichlorophenol. L-Alanine is used as a sole nitrogen source, but not acetamide, L-asparagine, L-aspartate, 2,4-dinitrophenol, D-glucosamine, or L-serine. Does not grow in the presence of lysozyme, or sodium chloride (4.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids co-migrate with those of the type strain of *Rhodococcus marinonascens*. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: soil collected from Maanshan Mountain in Anhui Province, China.

DNA G+C content (mol%): 66.2 (T_m).

Type strain: M712, AS 4.1720, DSM 44675, JCM 11374, NBRC 100610.

Sequence accession no. (16S rRNA gene): AF416566.

Sequence accession no. (gyrB): AB262519.

18. **Rhodococcus marinonascens** Helmke and Weyland 1984, 137[VP]

ma.ri.no.nas′cens. L. adj. *marinus* of the sea; L. part. adj. *nascens* born. N.L. part. adj. *marinonascens* born of the sea.

Gram-stain-positive, partially acid-fast actinomycete. Forms a well developed branched primary mycelium that fragments into bacillary and coccoid elements on solid media. Irregularly wrinkled, cream-colored colonies, which are sometimes tinged with pink, are formed on yeast extract agar. Optimal growth occurs at 20°C and in media with 75–10% seawater content or an equivalent salt concentration. Degrades arbutin and L-tyrosine, but not adenine, casein, cellulose, chitin, elastin, or xylan. Nitrate is not reduced to nitrite. Acid is produced from fructose, glucose, inositol, inulin, and mannose, but not from cellobiose, dulcitol, ethanol, galactose, glycogen, lactose, maltose, mannitol, melezitose, raffinose, rhamnose, salicin, sucrose, trehalose, or xylose. Acetate, gluconate, malate, pyruvate, and succinate are used as sole carbon sources, but not ethanol, turanose, xylitol, benzoate, citrate, *p*-cresol, *p*-hydroxybenzoic acid, lactate, pimelate, sebacate, or testosterone. D- and L-Alanine are used as sole nitrogen sources, but not L-glycine, or L-proline. Resistant to crystal violet (0.01%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), sodium azide (0.02%, w/v), and sodium chloride (7.0%, w/v), but susceptible to lysozyme. Additional phenotypic features are shown in Table 44. Mycolic acids have 34–50 carbon atoms.The fatty acid profile is shown in Table 47. The major menaquinoine is MK-8(H_2).

Source: the uppermost layer of marine sediments from the North East Atlantic.

DNA G+C content (mol%): 65–66 (T_m).

Type strain: 3438W, ATCC 35653, CIP 104177, DSM 43752, NBRC 14363, JCM 6241, NRRL B-16940, VKM Ac-1182.

Sequence accession no. (16S rRNA gene): X80617.

Sequence accession no. (gyrB): AB014115.

19. **Rhodococcus opacus** Klatte, Kroppenstedt and Rainey 1994a, 357[AL]

o.pa′cus. L. masc. adj. *opacus* shady, nontransparent.

Gram-stain-positive, non-acid-fast actinomycete. Forms a branched substrate mycelium that fragments into bacillary and coccoid elements in stationary phase. Cream-gray colored colonies have an entire margin and a smooth to rough surface; they develop a depressed center after several days of growth. Positive for catalase and *p*NP-phosphoryl-choline, but negative for 2-deoxythymidine-5′-*p*NP-phosphate, oxidase, and *p*NP-β-D-xyloside. Degrades adenine, L-tyrosine, and uric acid, but not arbutin, casein, cellulose, elastin, gelatin, or starch. Nitrate is reduced to nitrite. Acid is produced from fructose, glucose, inositol, lactose, maltose, mannitol, and sorbitol, but not from mannose. D-Arabitol, 2,3-butylene glycol, *n*-hexadecane, D-psicose (weak), *n*-tetradecane, turanose, *n*-undecane, xylitol, acetate, *N*-acetyl-D-glucosamine, γ-aminobutyrate, benzoate, caprate, citrate, gluconate, 3- and 4-hydroxybenzoate, *p*-hydroxybenzoic acid, 2-hydroxyvalerate, 2-oxyglutarate, phenylacetate, pimelate, shikimate, succinate, and quinate are used as sole carbon sources, but not adonitol, amygdalin, D-arabinose, α-cyclodextrin, dulcitol, ethanol, L-fucose, gentiobiose, D-galacturonic acid, lactulose, methyl-β-D-galactoside, methyl-α-D-mannoside, salicin, stachyose, glutarate, lactate, D-lactic acid methyl ester, malate, or propionate. D- and L-Alanine, L-aspartate, barbituric acid, cytosine, D-glucosamine, L-leucine, L-proline, putrescine, L-serine, thymine, trimethylenediamine, tyramine, urea, uric acid, and valine are used as sole nitrogen sources, but not acetamide, 2,4-dinitrophenol, *p*-nitrophenol, orotic acid, L-phenylalanine, L-pyroglutamic acid, uracil, or uridine-5′-monophosphate. Resistant to lysozyme and sodium chloride (5.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 48–54 carbon atoms. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: soil.

DNA G+C content (mol%): 67.6 (HPLC).

Type strain: DSM 43205, ATCC 51881, CIP 104549, DSM 43205, NBRC 16217, JCM 9703, NBRC 100624.

Sequence accession no. (16S rRNA gene): X80630.

Additional remarks: strains can degrade aromatic compounds, notably aromatic carboxylic acids, catechols, and substituted phenols, phthalic acid esters, and pyridine. Some strains have the ability to utilize gaseous hydrocarbons as sole carbon sources resulting in the production of subterranean petroleum deposits.

20. **Rhodococcus percolatus** Briglia, Rainey, Stackebrandt, Schraa and Salkinoja-Salonen 1996, 29VP

per.co.la′tus. L. pref. *per* very, thoroughly, completely; L. part. masc. adj. *colatus* filtered; N.L. masc. adj. *percolatus* completely filtered, referring to the percolator system used for isolation.

Gram-stain-positive actinomycete. Forms a primary mycelium that fragments into rod–coccus elements, and shows snapping division and v-forms. Colonies are light pink. Positive for 2-deoxythymidine-5′-*p*NP-phosphate and *p*NP-β-D-xyloside, but negative for oxidase. Degrades L-tyrosine, Tweens 20 and 40, and uric acid, but not adenine, arbutin, casein, elastin, or starch. Amygdalin, D-arabitol, 2,3-butylene glycol, gentiobiose, methyl-β-D-galactoside, methyl-β-D-glucoside, D-psicose, salicin, turanose, xylitol, acetate, *N*-acetyl-D-glucosamine, γ-aminobutyrate, benzoate, caprate, citrate, fumarate, D-galacturonic acid, lactone, gluconate, L-glutamic acid, 3- and 4-hydroxybenzoate, *p*-hydroxybenzoic acid, α-hydroxybutyric acid, *m*- and *p*-hydroxyphenylacetic acid, 2-hydroxyvalerate, α-ketobutyric acid, lactate, malate, methyl pyruvate, monoethanolamine, monomethyl succinate, mucate, 2-oxyglutarate, phenylacetate, pimelate, propionate, pyruvate, D-saccharic acid, and succinate are used as sole carbon sources, but not *N*-acetyl-β-D-mannoside, adonitol, D-arabinose, α-cyclodextrin, dulcitol, ethanol, D-fructose-6-phosphate, L-fucose, D-galacturonic acid, α-D-glucose-1-phosphate, glucose-6-phosphate, DL-α-glycerol phosphate, inosine, lactulose, lyxose, maltotriose, α-methyl-D-galactoside, methyl-α-D-mannoside, propylene glycol, stachyose, acetoacetic acid, L-galacturonic acid lactone, D-glucuronic acid, glutarate, glycollate, glyoxylic acid, D-lactic acid methyl ester, tartrate, or tricarballylic acid. Acetamide, D-and L-alanine, L-asparagine, L-aspartate, L-aspartic acid, 2,4-dinitrophenol, D-glucosamine, L-glutamine, L-leucine, phenylethylamine, L-proline, putrescine (weak), D-threonine, and tyramine are used as sole nitrogen sources, but not adenosine, L-alanyl-glycine, D-aspartic acid, 2′-deoxyadenosine, glucuronamide, glycyl-L-aspartic acid, glycyl-L-glutamic acid, glycyl-L-proline, *p*-nitrophenol, L-pyroglutamic acid, D- or L-serine, L-threonine, thymidine, or uridine-5′-monophosphate. Grows in the presence of sodium chloride (5.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 46–54 carbon atoms. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. The major menaquinone is MK-8(H_2).

Source: a 2,4,6- trichlorophenol enrichment culture in a percolator inoculated with contaminated sludge and sediment samples.

DNA G+C content (mol%): 67.4 (HPLC).

Type strain: MBS1, JCM 10087, NBRC 100626).

Sequence accession no. (16S rRNA gene): X92114.

Additional remarks: strains are able to produce extracellular surfactants, degrade pyridine and can grow on phenol and a range of xenobiotic compounds, including 2,3-dichlorophenol, 3,4-dichlorophenol, 2,4,5-trichlorophenol, 2,3,6-trichlorophenol, toluene, and 2,4,6-trichlorophenol.

21. **Rhodococcus phenolicus** Rehfuss and Urban 2005, 698AL

phe.nol.i′cus. N.L. n. *phenol* common name for the industrial solvent hydroxybenzene; L. suff. *-icus -a -um*, suffix used with the sense of belonging to; N.L. masc. adj. *phenolicus* pertaining to phenol.

Gram-stain-positive actinomycete which forms an extensive substrate mycelium that fragments into rods and cocci of variable size during later growth phases. Colonies develop a deep pink pigmentation during stationary phase with a varied morphological appearance that can be observed on tryptic soy agar. Most colonies are rugose and radiate in texture with an undulate margin and an umbonate elevation, a minority have a mucoid and smooth appearance. Grows well at pH 6.0–8.0 and moderately well at pH 4.0 and 10.0. Catalase-positive. Oxidase-negative. Nitrate is reduced to nitrite, but does not hydrolyze arbutin or produce hydrogen sulfide. Does not degrade DNA. Biphenyl (weak), chlorobenzene, chlorobenzoic acid, 1,4-dichlorobenzene, toluene (weak), and phenol are used as sole carbon sources, but not L-arabinose, inulin, lactose, raffinose, starch, or D- or L-xylose. Additional phenotypic features are shown in Table 45. The fatty acid profile is shown in Table 48.

Source: Johnson Space Center graywater bioprocessor.

DNA G+C content (mol%): 66.7 (HPLC).

Type strain: G2P, DSM 44812, JCM 14914, NRRL B-24323.

Sequence accession no. (16S rRNA gene): AY533293.

Additional remarks: aerial mycelia are formed when grown on chlorobenzene, chlorobenzoic acid, 1,4-dichlorobenzene, and phenol as sole carbon sources.

22. **Rhodococcus pyridinivorans** Yoon, Kang, Cho, Lee, Kho, Kim and Park 2000b, 2178VP

py.ri.di.ni.vo′rans. N.L. n. *pyridinum* pyridine; L. v. *vorare* to devour; N.L. part. adj. *pyridinivorans* pyridine-devouring.

Gram-stain-positive, branched filaments fragment into short rods and cocci. Colonies on tryptic soy agar are light orange, opaque, raised with slightly irregular edges. Grows at 10–45°C but not at 50°C. Grows at pH 6.0–9.0. Catalase-positive. Oxidase-negative. Hydrolyzes arbutin, produces hydrogen sulfide, reduces nitrate to nitrite, but does not degrade DNA or uric acid. Does not produce acid from L-arabinose, cellobiose, galactose, inulin, lactose, raffinose, or rhamnose. L-Arabitol, biphenyl, glycerol, mannose, starch, toluene, xylitol, γ-aminobutyrate, fumarate, and γ-hydroxybutyric acid are used as sole carbon sources, but not L-arabinose, arbutin, dulcitol, inulin, lactose, α-methyl-D-galactoside, raffinose, D- or L-xylose, benzoate, formate, hippurate, monoethanolamine, phenol, or tartrate. L-Leucine is used as a sole nitrogen source. Utilizes high concentrations (3500 mg l<MIN>1) of pyridine. Additional phenotypic features are shown in Table 45. Mycolic acids have 36–46 carbon atoms. The fatty acid pattern is shown in Table 48. The major menaquinone is MK-8(H_2).

Source: industrial wastewater in Korea.

DNA G+C content (mol%): 66 (HPLC).

Type strain: PDB9, DSM 44555, JCM 10940, KCC M80005, KCTC 0647BP, NBRC 100608.

Sequence accession no. (16S rRNA gene): AF173005.

Sequence accession no. (gyrB): AB088665.

23. **Rhodococcus qingshengii** Xu, He, Wang, Wang, Li, Tang and Li 2007, 2756[VP]

qing.shen′gi.i. N.L. gen. masc. n. *qingshengii* of Qing-Sheng, to honor Qing-Sheng Fan, a respected Chinese microbiologist, for his many contributions to the development of microbiology in China.

Gram-stain-positive actinomycete which forms an elementary mycelium that fragments into short rods and cocci. Colonies on Luria–Bertani agar are orange, opaque, and convex with irregular edges. Catalase-positive. Oxidase-negative. Does not reduce nitrate. Degrades carbendazim, Tween 40, but not starch. Catechol, dextrin, D-psicose, acetate, gluconate, α-ketovaleric acid, and malate are used as sole carbon sources, but not turanose, xylitol, α-, β-, or γ-hydroxybutyric acid, lactate, or methyl pyruvate. Alaninamide, L-alanine, L-alanyl-glycine (weak), benomyl, carbendazim, and urea are used as sole nitrogen sources, but not L-asparagine. Resistant to sodium nitrite (0.02%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids are present. The fatty acid profile is shown in Table 47. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylinositol, and phosphatidylmethylethanolamine. The major menaquinone is MK-8(H_2).

Source: carbendazim-contaminated soil from Jiangsu Province, China.

DNA G+C content (mol%): 59.1 (T_m).

Type strain: djl-6, CGMCC 1.6580, JCM 15477, KCTC 19205.

Sequence accession no. (16S rRNA gene): DQ090961.

24. **Rhodococcus rhodnii** Goodfellow and Alderson 1979, 80[VP] (Effective publication: Goodfellow and Alderson 1977, 117.)

rhod′ni.i. N.L. masc. n. *Rhodnius* generic name of the reduvid bud; N.L. gen. n. *rhodnii* of *Rhodnius*.

Gram-stain-positive actinomycete which forms a primary mycelium that fragments into short rods and cocci. Rough, red colonies are formed on glucose-yeast extract agar. Grows at 25–37°C. Catalase-positive, but does not hydrolyze allantoinase, 2-deoxythymidine-5′-*p*NP-phosphate, *p*NP-phosphoryl-choline, or *p*NP-xyloside. Oxidase-negative. Produces hydrogen sulfide, but does not hydrolyze arbutin or reduce nitrate to nitrite. Does not degrade adenine, cellulose, chitin, DNA, elastin, Tweens 20, 40, or 60, or xylan. Does not produce acid from L-arabinose, cellobiose, galactose, inulin, lactose, raffinose, or rhamnose. D-Arabitol, mannose, D-xylose (weak), adipate, benzoate, caprate, *p*-cresol, fumarate, 2-hydroxyvalerate, lactate, malate, octanoate, 2-oxyglutarate, pimelate, propionate, and sebacate are used as sole carbon sources, but not L-arabinose, biphenyl, 2,3-butylene glycol, glycerol, lactose, propylene glycol, raffinose, starch, toluene, turanose, L-xylose, *N*-acetyl-D-glucosamine, γ-aminobutyrate, glutarate, 3- and 4-hydroxybenzoate, phenol, phenylacetate, tartrate, testosterone, or quinate. L-Leucine, L-proline, and L-tyrosine are used as sole nitrogen sources, but not L-alanine, L-aspartate, D-glucosamine, putrescine, D- or L-serine, ornithine, trimethylenediamine, tyramine, or valine. Grows in the presence of crystal violet (0.001%, w/v), phenol (0.1%, w/v), sodium azide (0.02%, w/v), and sodium chloride (7.0%, w/v). Additional phenotypic features are shown in Table 45. Mycolic acids have 38–52 carbon atoms. The fatty acid profile is shown in Table 48.

Type strain: N445, ATCC 35071, CIP 104181, DSM 43336, IEGM 555, JCM 3203, KCC A-0203, LMG 5363, NBRC 100604, NCIB (now NCIMB) 11279, NRRL B-16535, VKM Ac-1187.

Sequence accession no. (16S rRNA gene): X80621.

Sequence accession no. (gyrB): AB014254.

25. **Rhodococcus ruber** (Kruse 1896) Goodfellow and Alderson 1979, 80[VP] (Effective publication: Goodfellow and Alderson 1977, 117; *Streptothrix rubra* Kruse 1896, 63.)

ru′ber. L. masc. adj. *ruber* red.

Gram-stain-positive actinomycete. Forms a primary mycelium that fragments into rods and cocci. Single unbranched aerial hyphae produced. Rough, pink to red colonies are formed on glucose-yeast extract agar, Sauton's agar, and egg media. Grows at 28–40°C. Positive for acetamidase, catalase, 2-deoxythymidine-5′-*p*NP-phosphate, and *p*NP-phosphoryl-choline, but negative for acid phosphatase, allantoinase, α- and β-esterase, β-galactosidase, and *p*NP-β-D-xyloside. Produces hydrogen sulfide, reduces nitrate to nitrite, but is oxidase-negative. Degrades adenine and uric acid, but not cellulose, chitin, DNA, elastin, Tweens 20, 40, and 60, or xylan. Unable to hydrolyze arbutin. Acid is produced from glucose, mannitol, and sorbitol, but not from L-arabinose, cellobiose, galactose, inositol, inulin, lactose, mannose, raffinose, rhamnose, or trehalose. D- and L-Arabitol, biphenyl (weak), *iso*-butanol, glycerol, inulin, mannose, propan-1-ol, propylene glycol, starch, toluene, xylitol, adipate, γ-aminobutyrate, benzoate, caprate, *p*-cresol, fumarate, L-glutamic acid, 3- and 4-hydroxybenzoate, γ-hydroxybutyric acid, lactate, malate, malonate, monoethanolamine, octanoate, 2-oxyglutarate, phenylacetate, pimelate, propionate, sebacate, testosterone, and quinate are used as sole carbon sources, but not L-arabinose, arbutin, dulcitol, lactose, α-methyl-D-galactoside, raffinose, turanose, D- and L-xylose, *N*-acetyl-D-glucosamine, glutarate, 2-hydroxyvalerate, or phenol. L-Alanine, D-glucosamine, L-leucine, putrescine, tyramine, L-tyrosine, and valine are used as sole nitrogen sources, but not L-aspartate, L-proline, D- and L-serine, or trimethylenediamine. Resistant to crystal violet (0.001%, w/v), phenol (0.1%, w/v), phenyl ethanol (0.3%, v/v), picric acid (0.2%, w/v), sodium azide (0.01%, w/v), sodium chloride (7.0%, w/v), sodium nitrate (0.1%, w/v), and sodium salicylate (0.1%, w/v), but susceptible to lysozyme, 5-fluorouracil (5 µg per ml), mitomycin (5 µg per ml), and rifampin (25 µg per ml). Additional phenotypic features are shown in Table 45. Mycolic acids have 38–50 carbon atoms. The fatty acid profile is shown in Table 47. Major menaquinone is MK-8(H_2).

Source: soil.

DNA G+C content (mol%): 65–69 (T_m).

Type strain: KCC A-0205, CIP 104180, DSM 43338, IEGM 70, NBRC 15591, JCM 3205, LMG 5366, VKM Ac-1021.

Sequence accession no. (16S rRNA gene): X80625.

Sequence accession no. (gyrB): AB014174.

Additional remarks: strains can use gaseous hydrocarbons as sole carbon sources, degrade aromatic compounds, form biosurfactants that facilitate oil removal from soil and produce poly(3-hydroxyalkanoic) acids of value in the production of biodegradable plastic.

26. **Rhodococcus triatomae** Yassin 2005, 1578[VP]

tri.a.to'ma.e. N.L. gen. n. *triatomae* of *Triatoma*, a genus of blood-sucking bug from which the micro-organism was isolated.

Gram-stain-positive, slightly acid–alcohol-fast actinomycete. Produces thin filamentous cells and shows a primary mycelium that fragments into rods and cocci. White to creamy colonies with slightly irregular edges are produced on Columbia blood agar. Grows at 22–42°C. Degrades adenine, but not elastin, gelatin, or guanine. Testosterone is used as a sole carbon source, but not adipate, amyl-alcohol, L-arabinose, 2,3-butylene glycol, erythritol, lactate, lactose, propylene glycol, raffinose, or L-xylose. Urea is used as a sole nitrogen source, but not L-alanine, L-arginine, gelatin, L-proline, L-serine, or ornithine. Additional phenotypic features are shown in Table 45. Mycolic acids present. The fatty acid pattern is shown in Table 48. The major menaquinone is MK-8(H_2).

Source: a blood-sucking bug of the genus *Triatoma*.

DNA G+C content (mol%): not determined.

Type strain: IMMIB RIV-085, CCUG 50202, DSM 44892, NBRC 103116.

Sequence accession no. (16S rRNA gene): AJ854055.

27. **Rhodococcus tukisamuensis** Matsuyama, Yumoto, Kudo and Shida 2003, 1334[VP]

tu.ki.sa.mu.en'sis. N.L. masc. adj. *tukisamuensis* of or belonging to Tukisamu, a town in Sapporo, Hokkaido, Japan where the type strain was isolated.

Gram-stain-positive, non-acid-fast actinomycete. Forms a primary mycelium that fragments into rods and cocci. Opaque cream colored colonies with irregular edges are produced on tryptic soy agar. Growth occurs at 15–45°C and pH 5.5–8.5. Catalase-positive. Oxidase-negative. Hydrolyzes arbutin, reduces nitrate, but does not produce hydrogen sulfide. Does not degrade adenine, casein, elastin, hypoxanthine, starch, L-tyrosine, uric acid, or xanthine. Does not produce acid from adonitol, L-arabinose, cellobiose, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, ribose, salicin, sorbitol, sucrose, trehalose, or xylose. Adonitol, dulcitol, turanose, xylitol, succinate, and testosterone are used as sole carbon sources, but not D-arabinose or citrate. Resistant to sodium chloride (4.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 44–52 carbon atoms. The fatty acid profile is shown in Table 47. The major menaquinone is MK-8(H_2).

Type strain: Mb8, JCM 11308, NBRC 100609, NCIMB 13903.

Sequence accession no. (16S rRNA gene): AB067734.

Sequence accession no. (gyrB): AB262518.

28. **Rhodococcus wratislaviensis** (Goodfellow, Zakrzewska-Czerwinska, Thomas, Mordarski, Ward and James 1995) Goodfellow, Chun, Stackebrandt and Kroppenstedt 2002, 752[VP] (*Tsukamurella wratislaviensis* Goodfellow, Zakrzewska-Czerwinska, Thomas, Mordarski, Ward and James 1995; *Tsukamurella wratislaviensis* Goodfellow, Zakrzewska-Czerwinska, Thomas, Mordarski, Ward and James 1991b)

wra.tis.la.vi.en'sis. N.L. masc. adj. *wratislaviensis* of or pertaining to Wratislavia (Wroclaw, Poland).

Gram-stain-positive, acid–alcohol-fast actinomycete. Forms straight to slightly curved rods. Colonies are white to creamy and irregular. Grows at 10–37°C and at pH 5–9. Cleaves 4-methylumbelliferyl (4MU)-2-acetoamido-2-deoxy-β-D-glucopyranoside, 4MU-α-L-arabinopyranoside, benzyloxycarbonyl-L-alanine-L-alanine-L-phenylalanine-7-amino-methylcoumarin (7AMC), benzyloxycarbonyl-L-arginine-7AMC, benzyloxycarbonyl-L-arginine-L-arginine-7AMC, benzyloxycarbonyl-L-phenylalanine-arginine-7AMC, 4MU-β-D-cellopyranoside, 4MU-elaidate, 4MU-heptanoate, *iso*-leucine-7AMC, L-lysine-7AMC, L-methionine-7AMC, 4MU-nonoate, 4MU-oleate, 4MU-palmitate, 4MU-phosphate, 4MU-*bis*-phosphate, 4MU-pyrophosphate, L-serine-7AMC, 4MU-stearate, succinyl-benzylcysteine-7AMC, 4MU-sulfate, L-tyrosine-7AMC, and L-valine-7AMC, but not 2-deoxythymidine-5′-*p*NP-phosphate, *p*NP-phosphoryl-choline, or *p*NP-β-D-xyloside. Degrades L-tyrosine and uric acid, but not adenine or arbutin. Amyl-alcohol, D-arabinose, *iso*-butanol, butane-1,3-diol, ethanol, L-fucose (weak), gentiobiose (weak), paraffin, D-psicose, salicin, stachyose, turanose, acetate, *N*-acetyl-D-glucosamine androsterone, benzoate, citraconic acid, citrate, fumarate, gluconate, 3- and 4-hydroxybenzoate, *m*- and *p*-hydroxybenzoic acid, 2-hydroxyvalerate, malate, D-mandelic acid, pimelate, propionate, pyruvate, sebacate, testosterone, and vanillin are used as sole carbon sources, but not adonitol, amygdalin, D-arabitol, 2,3-butylene glycol, α-cyclodextrin, dulcitol, D-galacturonic acid, lactulose, methanol, methyl-β-D-galactoside, methyl-α-D-mannoside, γ-aminobutyrate, anthranilic acid, caprate, glutarate, lactate, D-lactic acid methyl ester, 2-oxyglutarate, phenylacetate, succinate, or tartrate. D- and L-Alanine, L-asparagine, L-aspartate, betaine, D-glucosamine, L-leucine, DL-norleucine, L-phenylalanine, L-proline, putrescine, L-serine, spermine, and uridine-5′-monophosphate are used as sole nitrogen sources, but not acetamide, 2,4-dinitrophenol, *p*-nitrophenol, L-pyroglutamic acid, L-threonine, or tyramine. Grows in the presence of crystal violet (0.001%, w/v) and sodium chloride (5.0%, w/v), but not in the presence of phenol (0.001%, w/v), phenyl ethanol (0.3%, v/v), and sodium azide (0.001%, w/v). Resistant to (μg per ml) gentamicin (16), neomycin (9), novobiocin (2), oleandomycin (32), penicillin (32), polymyxin (32), rifampin (4), streptomycin (4), tobramycin (8), and vancomycin (4) but sensitive to chloramphenicol (32), chlorotetracycline (4), and vancomycin (4). Additional phenotypic features are shown in Table 44. Mycolic acids have 46–54 carbon atoms with up to three double bonds. The fatty acid profile is shown in Table 47. The major menaquinone is MK-8(H_2).

Source: soil.

Sequence accession no. (gyrB): AB014315.

29. **Rhodococcus yunnanensis** Zhang, Li, Kroppenstedt, Kim, Chen, Park, Xu and Jiang 2005, 1135[VP]

yun.nan.en′sis. N.L. masc. adj. *yunnanensis* of or pertaining to Yunnan, a province of south-west China.

Gram-stain-positive actinomycete. Forms hyphae that fragment into short-rods and coccobacilli. Smooth, opaque pale yellow to orange colonies (0.5–1.0 mm in diameter) are formed on yeast extract-malt extract, tryptic-soy, and peptone-yeast extract-glucose agars. Grows at 10–40°C and optimally at 28–30°C. Optimum pH for growth is 7.0–8.0. Positive for *N*-acetyl-β-glucosaminidase, alkaline phosphatase, α- and β-galactosidase, β-glucosidase, β-glucuronidase, and lipase, but negative for acid phosphatase, cystine arylamidase, esterase lipase (C8), naphthol-AS-BI-phosphohydrolase, and valine arylamidase. Degrades Tweens 20 and 40, but not gelatin, milk, or starch. Does not reduce nitrate to nitrite. Acid is produced from acetamide. Assimilates *N*-acetyl-D-glucosamine as a sole carbon source. Acetamide is used as a sole nitrogen source. Grows in the presence of sodium chloride (12.0%, w/v). Additional phenotypic features are shown in Table 44. Mycolic acids have 44–52 carbon atoms. The fatty acid profile is shown in Table 47. The predominant menaquinone is MK-8(H_2).

Source: forest soil collected from Yunnan Province, China.

DNA G+C content (mol%): 63.5 (T_m).

Type strain: YIM 70056, CCTCC AA 204007, DSM 44837, JCM 13366, KCTC 19021, NBRC 103083, NBRC 103115.

Sequence accession no. (16S rRNA gene): AY602219.

30. **Rhodococcus zopfii** Stoecker, Herwig and Staley 1994, 109[VP]

zop′fi. i. N.L. masc. gen. n. *zopfii* of Zopf, named in honor of Wilhelm Friedrich Zopf, who described the bacterium *Rhodococcus rhodochrous.*

Gram-stain-positive actinomycete. Forms an extensive branched mycelium that fragments into irregular rod-shaped to coccoid cells. Colonies on glucose-yeast extract agar are red-orange and wrinkled. Catalase-positive. Oxidase-negative. Nitrate is reduced to nitrite. Does not produce hydrogen sulfide. Degrades DNA and uric acid. Does not produce acid from L-arabinose, cellobiose, galactose, inulin, lactose, raffinose, or rhamnose. L-Arabitol, arbutin, biphenyl, glycerol, mannose, α-methyl-D-galactoside, toluene, xylitol, γ-aminobutyrate, benzoate, fumarate, γ-hydroxybutyric acid, monoethanolamine, and sebacate are used as sole carbon sources, but not dulcitol, starch, D-xylose, or phenol. L-Leucine is used as sole nitrogen source. Resistant to phenol (0.02%, w/v). Additional phenotypic features are shown in Table 45. Mycolic acids have 33–36 carbon atoms. The fatty acid profile is shown in Table 48.

Source: a toluene-phenol bioreactor operated by the Department of Civil Engineering, University of Washington, WA, USA.

DNA G+C content (mol%): 70 (T_m).

Type strain: T1, ATCC 51349, CIP 104275, DSM 44108, JCM 9919, NBRC 100606, NRRL B-16942.

Sequence accession no. (16S rRNA gene): AF191343.

Sequence accession no. (gyrB): AB014176.

Additional remarks: utilizes biphenyl, phenol, and toluene.

Genus V. **Skermania** Chun, Blackall, Kang, Hah and Goodfellow 1997, 129[VP]

Michael Goodfellow

Sker.man′i.a. N.L. n. *Skermania* named after Victor Bruce Darlington Skerman (1921–1993), a celebrated Australian bacterial systematist.

Gram-stain-positive, non-acid-fast, nonmotile, non-sporeforming, facultative aerobic actinomycetes which **form an extensive substrate mycelium that does not fragment in undisturbed cultures**; secondary branching is rare or absent. **Short branched and unbranched aerial hyphae are visible microscopically, but not to the naked eye**. **During early stages of growth the microscopic appearance of the organism resembles a pine tree**. Colonies are orange, opaque, macroscopically dry and friable. Chemo-organotrophic with an oxidative type of metabolism. Catalase-, oxidase-, and urease-positive. Grows between 15° and 31°C.

Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid, arabinose, galactose, glucose, and ribose. The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-glycolated. **Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major phospholipids, large amounts of straight-chain saturated, unsaturated and 10-methyloctadecanoic (tuberculostearic) fatty acids, and predominant amounts of hexahydrogenated menaquinones with eight isoprene units where the last two are cyclicized**. **Mycolic acids have 58–64 carbon atoms, 2–6 double bonds, and monounsaturated side chains. The fatty acid esters released on pyrolysis gas chromatography of mycolic acid esters have 16–20 carbon atoms.** The phylogenetic position of *Skermania,* as determined by 16S rRNA gene sequence analysis, is in the family *Gordoniaceae.*

The organism grows as an extensive surface scum or foam on the surfaces of aeration tanks and in mixed liquors of activated sludge plants.

DNA G+C content (mol%): 67.5 (T_m).

Type species: **Skermania piniformis** Chun, Blackall, Kang, Hah and Goodfellow 1997, 129[VP].

Further descriptive information

Phylogeny. The genus *Skermania* contains a single species, *Skermania piniformis*, which falls towards the periphery of the 16S rRNA gene tree containing genera formerly classified in the family *Gordoniaceae* (see Figure 93 in *Gordonia*, above).

Cell morphology. *Skermania piniformis* was originally called the Pine-Tree Like Organism (PTLO) because of its distinctive tree-like microscopic morphology at the beginning of the growth cycle (Blackall et al., 1988, 1989). The branching angles of skermaniae are acute, rather than right-angled as in *Gordonia amarae*, and branches near the apex are shorter than those further away. The mycelium of *Skermania piniformis* does not fragment in undisturbed cultures and secondary branching is rare. Aerial mycelium is not visible to the naked eye, but short branched and unbranched aerial hyphae can be seen microscopically. Microcolonies show the presence of phase bright spherical regions at terminal and intercalary positions in the mycelium. The septate mycelia of skermaniae taper after branch points.

The original description of *Skermania piniformis* was based on a few strains and a small number of physiological properties (Blackall et al., 1989). Subsequently, additional strains which showed the branching morphology characteristic of the PTLO were found to have a distinctive API ZYM pattern (Soddell and Seviour, 1994). These strains exhibited considerable variations in branching angles, branching lengths, and interbranching distances, but formed a homogeneous cluster together with the type strain of *Skermania piniformis* in an extensive numerical taxonomic survey of actinomycetes isolated from activated sludge (Soddell and Seviour, 1998).

Cell wall composition. Skermaniae have (a) a peptidoglycan composed of *N*-acetylglucosamine, D-alanine, and D-glutamic acid with *meso*-diaminopimelic acid (*meso*-A_2pm) and muramic acid moieties that are *N*-glycolated; (b) arabinose and galactose as diagnostic sugars (i.e., whole-organism sugar pattern type A *sensu* Lechevalier and Lechevalier (1970); (c) a phospholipid pattern consisting of diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides (i.e., phospholipid pattern type II *sensu* Lechevalier et al., (1981b, 1977); (d) major amounts of straight-chain, unsaturated and methyloctadecanoic (tuberculostearic) fatty acids (i.e., a type IV fatty acid pattern *sensu* Lechevalier et al., 1977); (e) mycolic acids with 58–64 carbon units, 2–6 double bonds, and monounsaturated side chains (Blackall et al., 1989); and (f) predominant amounts of hexahydrogenated menaquinones with eight isoprene units where the last two are cyclicized (Blackall et al., 1989). The fatty acid profiles of skermaniae are particularly rich in hexadecanoic ($C_{16:0}$; 20–41%), hexadecenoic ($C_{16.1}$; 15–20%), octadecenoic ($C_{18:1}$; 20–32%), and 10-methyloctadecenoic (12–24%) acids (Blackall et al., 1989).

Colony morphology. Orange, opaque, circular colonies (1–2 mm in diameter) are formed on tryptone-yeast extract-glucose agar (Blackall et al., 1989). These workers found that the growth rate of colonies was variable for no apparent reason as on some occasions colonies were formed in 9–10 d, but in other instances the same strains took 21 d for colonies of the same size to develop. Colonies are macroscopically dry and friable, but are moist and shiny when observed under the microscope; they have a pasty texture, and are difficult to emulsify and culture. Whole colonies tend to remain intact when taken from the surface of agar plates.

Nutrition and growth conditions. Skermaniae have been cultivated on yeast extract, yeast extract-glucose, and tryptone-yeast extract-glucose agars (Blackall et al., 1989; Soddell and Seviour, 1998). They grow best on media containing glycerol as a carbon source and asparagine as a nitrogen source, features they have in common with mycobacteria (Ratledge, 1982). In tryptone-yeast extract-glucose broth, strains grow as macroscopically visible colonies in a slightly turbid liquid. They grow at 15° and 31°C, poorly above 28°C, but not at 10° or 40°C.

Metabolism. The classification of *Skermania piniformis* as a strict aerobe needs to be revisited in light of *in situ* microautoradiographic studies carried out by Eales et al. (2006). The organism does not behave as a strict aerobe in foam, as expected from pure culture studies (Chun et al., 1997), but has the metabolism of a facultative aerobe capable of anaerobic nitrate respiration, as all of the substrates were taken up under anoxic (NO_3^-) conditions. Also, uptake of substrates appears to be greater under aerobic than anoxic conditions. Eales and her colleagues also pointed out that an ability to take up a substrate in the absence of oxygen does not necessarily mean that it can grow in the absence of oxygen.

Skermaniae are positive for catalase, oxidase, and urease. In addition, they are positive for acid phosphatase, esterase, esterase lipase, α-glucosidase, leucine arylamidase, α-mannosidase, and phosphoamidase, but negative for the remaining API ZYM activities (Blackall et al., 1989). They have the capacity to cleave a broad range of 7-amino-4-methylcoumarin conjugated substrates (Chun et al., 1997), and can use a diverse range of compounds as sole carbon sources for energy and growth (Soddell and Seviour, 1998). There is evidence that skermaniae produce more biomass and grow much faster on hydrophobic substrates, such as oils, than on hydrophilic substrates like glucose (Soddell and Seviour, 1996).

Ecology. *Skermania piniformis* is abundant in foams on the surface of aeration tanks in activated sludge plants, a feature it has in common with *Gordonia amarae* (Blackall et al., 1988, 1989; Soddell and Seviour, 1994, 1998). Skermaniae are commonly associated with foaming in Australian activated sludge plants, particularly in the summer months (Blackall et al., 1988; Seviour et al., 1990; Soddell and Seviour, 1994, 1998), but there is evidence that they may be more widely distributed (de los Reyes et al., 2002; Eales et al., 2005; Jenkins et al., 1984, 1993; Soddell and Seviour, 1990; Soddell et al., 1993). Because of its slow growth (2–3 weeks compared with 4–7 d for *Gordonia amarae* and related mycolic acid-containing actinomycetes) it may have been overgrown, and hence overlooked, in earlier studies using dilution plating procedures. There is evidence that *Skermania piniformis* can have a very low growth rate in activated sludge (de los Reyes et al., 2002).

Eales et al. (2005) studied the *in situ* physiology of filamentous bacteria (Pine Tree Like Organisms) from two Danish activated sludge plants with a focus on their response to hydrophobic substrates. Microautoradiographic studies showed that

the PTLO were highly selective in their substrate utilization in foams as only oleic acid was assimilated out of eight tested substrates. Oleic acid was metabolized both aerobically and anaerobically, and a low uptake was detected under anoxic conditions with nitrate and nitrite as electron acceptors. Data acquired from a combination of *in situ* techniques indicated that a high proportion of the PTLO were metabolically inactive in the foam. Most showed low respiratory activity as detected with the redox dye CTC and low intensity signals from fluorescence *in situ* hybridization (FISH) probing with 16S rRNA targeted probes. A strong correlation was observed between the accumulation of polyhydroxyalkanoates in filaments and the intensity of their fluorescent FISH signals.

In a further investigation, Eales et al. (2006) studied the *in situ* physiology of *Skermania piniformis* in foam samples taken from two geographically distinct Australian activated sludge plants. A 16S rRNA probe, Spin 1449, designed for the identification of *Skermania piniformis* by FISH was validated using pure cultures and applied to the foam samples. Filaments of the target organism appeared to be comparatively hydrophobic though no clear preference was shown for hydrophobic or hydrophilic substrates. Microautoradiographic studies showed that filaments selectively took up substrates under aerobic and anoxic (NO_3^-) conditions, but not under anaerobic or anoxic (NO_2^-) regimes. Eales and her colleagues concluded from their substrate uptake data that an anaerobic selector might prove to be effective in the control of *Skermania piniformis* in activated sludge systems.

The results from the *in situ* physiology study of *Skermania piniformis* differ markedly from those obtained from the Danish PTLO scum FISH-MAR experiments, as the *Skermania piniformis* strains from the Australian plants used a more diverse range of substrates albeit only in the presence of oxygen and nitrate. In contrast, the Danish PTLO were able to take up substrates under anaerobic and anoxic conditions with nitrite as an electron acceptor. These results suggest either that the PTLO associated with the Danish scums were members of mycolic acid-containing taxa other than *Skermania piniformis* or that important physiological differences exist between strains in the two countries. In either case, developing universal control strategies for *Skermania piniformis* may prove to be difficult.

The aerobic metabolic capabilities of *Skermania piniformis* in pure culture studies (Soddell and Seviour, 1998) are broader than those found in the *in situ* studies of Eales et al. (2006). Neither the hydrophilic substrates, glucose nor acetate, were taken up by *Skermania piniformis* under *in situ* conditions though other bacteria in the foams were able to do so. The differences from the pure culture data are in line with studies which show that bacteria in laboratory culture do not necessarily behave the same way as they do in complex natural habitats.

Isolation procedures

The first successful isolation of *Skermania piniformis* from activated sludge foam and mixed liquor involved the use of a micromanipulatory technique (Blackall et al., 1989). A Skerman micromanipulator (Skerman, 1968) was used to transfer acute angled, branching filaments from activated sludge samples, collected from plants in Queensland, Australia, onto either yeast extract-glucose agar or tryptone-yeast extract-glucose agar plates, which were incubated at a range of temperatures. Visible colonies of *Skermania piniformis* (1–2 mm in diameter) grew on the isolation plates within 10–21 d. Additional strains have been isolated from mixed liquor and foam samples from activated sludge plants across Australia using the Skerman micromanipulator, as described by Soddell and Seviour (1994).

Maintenance procedures

Skermaniae can be maintained and preserved using the procedures described for *Gordonia* strains.

Differentiation of the genus *Skermania* from other genera

Identification of *Skermania piniformis* is based on its distinctive morphology whereby individual filaments show acute angled branching patterns. The organism is currently the only validly published member of the order *Corynebacteriales* with the PTLO morphotype. However, similar branching patterns have been observed in pure cultures of *Rhodococcus* and *Tsukamurella* strains (Soddell and Seviour, 1994; Stainsby et al., 2002) thereby raising the possibility that some PTLO organisms may be members of unclassified mycolic acid-containing taxa. Consequently, skermaniae cannot be unambiguously recognized solely on the basis of morphology, especially since they exhibit a range of branching variations (Soddell and Seviour, 1994, 1998).

Skermania piniformis can be separated from other genera classified in the order *Corynebacteriales* (which have an oxidative metabolism and *N*-glycolated muramic acid moieties in the wall peptidoglycan) using a combination of chemotaxonomic and morphological features (Table 29, in the order *Corynebacteriales*, above), and by using the oligonucleotide probe, Spin 1449 (Eales et al., 2006). It can be distinguished from the other three genera assigned to the family *Gordoniaceae* using the probe and by its distinctive menaquinone profile.

Taxonomic comments

The monospecific genus *Skermania* was proposed by Chun et al. (1997) for organisms which had been designated first as Pine-Tree Like Organisms because of their distinctive tree-like microscopic morphology (Blackall et al., 1988, 1989) and then as *Nocardia pinensis* Blackall et al. 1989. The organism was assigned to the genus *Nocardia* on the basis of chemotaxonomic, morphological, and physiological properties, but its taxonomic position was equivocal given the presence of mycolic acids monounsaturated in the 2-position, a distinctive antibiotic sensitivity pattern, and a relatively slow growth rate. Initial 16S rRNA gene sequence data cast doubt on the association with the genus *Nocardia* (Blackall et al., 1994).

Chun and his colleagues found that an almost complete 16S rRNA gene sequence of the type strain of *Nocardia pinensis* showed almost equal levels of relatedness to corresponding sequences of *Gordonia* strains (levels of similarity, 94.9–95.9%), *Nocardia* strains (94.5–95.9%), and *Rhodococcus* strains (94.5–95.9%), and lower levels of homology with *Corynebacterium* strains (91.4–92.6%), *Tsukamurella* strains (93.7–93.8%), and to the type strain of *Dietzia maris* (91.4–92.6%). The results of additional 16S rRNA gene sequence analyses taken together with the discontinuous distribution of key chemical markers confirm the taxonomic status of the genus *Skermania* (Adachi et al.,

2007; Goodfellow et al., 1998a; Goodfellow and Maldonado, 2006; Soddell et al., 2006a). However, further comparative taxonomic studies are needed on *Skermania piniformis* and related strains as there is evidence that the genus may be underspeciated (Soddell and Seviour, 1998).

Acknowledgements

The author is indebted to Professor Robert J. Seviour (La Trobe University) for his expert advice on the ecology of *Skermania piniformis*.

List of species of the genus *Skermania*

1. **Skermania piniformis** (Blackall, Parlett, Hayward, Minnikin, Greenfield and Harbers 1989) Chun, Blackall, Kang, Hah and Goodfellow 1997, 129[VP] *Nocardia pinensis* Blackall, Parlett, Hayward, Minnikin, Greenfield and Harbers 1989, 1555).

pi. ni. for′ mis. N.L. n. *pinus*, a pine, pine-tree; L. adj. suffix – *formis*, *-is*, *-e* in the form of; N.L. fem. adj. *piniformis*, pine-like, pertaining to the pine-like appearance of young microcolonies.

Aerobic, Gram-stain-positive, non-acid-fast actinomycetes which during the early stages of growth (24 h) have a microscopic appearance that resembles a pine tree. Colonies (1–2 mm in diameter) form on tryptone-yeast extract-glucose agar within 10–21 d though growth is variable. Cells from activated sludge plants and from artificial culture media contain intracellular sudanophilic and polyphosphate inclusions.

Positive for acid phosphatase, esterase (C4), esterase lipase (C8), α-glucosidase, leucine arylamidase, α-mannosidase, and phosphoamidase in API ZYM tests. Does not hydrolyze esculin. Nitrate is not reduced. Degrades Tweens 20, 40, and 60, but not casein, elastin, gelatin, hypoxanthine, tyrosine, or xanthine. Fructose, glucose, glycerol, mannose, sucrose, and trehalose are used as sole carbon sources, but not arabinose, cellobiose, ethanol, galactose, inositol, inulin, lactose, maltose, mannitol, raffinose, rhamnose, sorbitol, or xylose (all at 0.1%, v/v). Similarly, acetate, butyrate, propionate, and pyruvate are used as sole carbon sources at 0.01%, w/v, but not acetamide, adipate, benzamide, benzoate, citrate, *p*-cresol, fumarate, gluconate, *m*-or *p*-hydroxybenzoate, lactate, malate, octanoate, pimelate, succinate, tartrate, testosterone, or tyrosine. Does not use acetamide, serine, or trimethylamine as sole carbon and nitrogen sources.

Sensitive to (μg/ml) 5-fluorouracil (20), isoniazid (2), lysozyme (50), mitomycin C (5), or rifampin (20) when glycerol broth is used as the basal medium. Grows in the presence of sodium azide (0.02%, w/v), sodium chloride (7%, w/v), and penicillin (10 IU).

Forms an extensive surface scum or foam on the surface of aeration tanks of activated sludge plants.

DNA G+C content (mol%): 65.7 (T_m).

Type strain: ATCC 49497, CIP 104516, UQM 3063, DSM 43998, IFO (now NRBC) 15059.

Sequence accession no. (16S rRNA gene): Z35435.

Genus VI. **Smaragdicoccus** Adachi, Katsuta, Matsuda, Peng, Misawa, Shizuri, Kroppenstedt, Yokota and Kasai 2007, 300[VP]

Hiroaki Kasai

Sma.rag.di.coc′cus. L. n. *smaragdus* malachite; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos*) grain; N.L. masc. n. *Smaragdicoccus* malachite(-colored) coccus.

Coccoidal cells without branching (0.86 μm in diameter). Stain Gram-positive, do not form spores. Multiply by binary fission. **Nonmotile**. **Colonies are malachite green-like colored**, round, and 1–3 mm in diameter after 7–14 d on 1/10 TSA at 30°C. The cell wall contains *meso*-diaminopimelic acid and arabinose and galactose, corresponding to the chemotype IV-A of Lechevalier and Lechevalier (1970). Cell wall acyl type is glycolyl. Predominant cellular fatty acids are straight-chain saturated and monounsaturated acids. 10-methyl branched acids are in trace amounts. Mycolic acids are C_{43}–C_{49}. Polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, phosphatidylinositol mannoside and some glycolipids. Two unusual menaquinones are present, MK-8(H_4, ω-methylenecycl) and MK-8(H_4, dicycl).

DNA G+C content (mol%): 63.7.

Type species: **Smaragdicoccus niigatensis** Adachi, Katsuta, Matsuda, Peng, Misawa, Shizuri, Kroppenstedt, Yokota and Kasai 2007, 300[VP].

Further descriptive information

Cells are regular cocci (Figure 97). The whole-cell hydrolysate contains *meso*-diaminopimelic acid, alanine, glutamic acid, as found in the cell-wall type A1γ of Schleifer and Kandler (1972). Following hydrolysis by the method of Uchida and Aida (1977), cell walls contain glycolyl residues. The components of the cell wall are similar to those of other members of the family *Nocardiaceae*. However, the cellular fatty acids are composed of

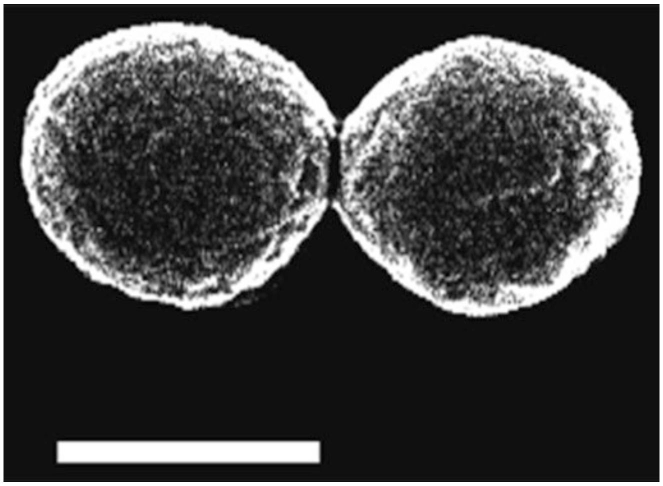

FIGURE 97. Scanning electron micrograph of cells of strain *Smaragdicoccus niigatensis* Hou_blue[T]. Cells grown for 14 d at 30°C on 1/10 TSA were fixed with 2.5 % glutaraldehyde. Bar, 1 µm.

straight-chain saturated and monounsaturated acids, and only traces of 10-methyl branched acids, which are common in the family *Nocardiaceae*, are present. Two cyclic menaquinones were detected by HPLC/PDA/MS/MS systems, one was MK-8(H_4, ω-methylenecycl) and the other was MK8 (H_4, dicycl) (Figure 98). MK-8(H_4, ω-methylenecycl) possessed the same UV and MS/MS profiles as MK-8(H_4, ω-cycl), which is diagnostic for *Nocardia* (Collins et al., 1987; Howarth et al., 1986). However, the ω-ring of the *Smaragdicoccus* menaquinone is 1,1-dimethyl-3-methylenecyclohexane and that of the *Nocardia* menaquinone is 1,5,5-trimethylcyclohex-1-ene (Figure 98). The 16S rRNA (AB243007) and *gyrB* (AB243008) gene sequences support the assignment of this genus to the family *Nocardiaceae*.

Enrichment and isolation procedures

Smaragdicoccus was isolated using hexadecane as the sole carbon source from an enrichment culture of petroleum-contaminated soil. The soil was found near a spurt of petroleum at Nishiyama-cho in Niigata, Japan. Malachite-green-like colored colonies appeared after 7 d on an inorganic medium (Peng et al., 2003) when incubated in a hexadecane-saturated atmosphere at 25°C.

Differentiation of the genus *Smaragdicoccus* from other genera

The results of 16S rRNA and *gyrB* gene sequence analyses (Figure 99), the cell-wall and peptidoglycan characterization, and the polar lipid analyses indicate that *Smaragdicoccus* belongs to the family *Nocardiaceae*. The profiles of quinones, fatty acids and mycolic acids indicate that *Smaragdicoccus* is an independent genus in this family.

Genus	Structure of menaquinone	Structure of ω-ring
Nocardia	 MK-8(H_4, ω-cycl)	 1,5,5-trimethylcyclohex-1-ene
Smaragdicoccus	 MK-8(H_4, ω-methylenecycl)  MK-8(H_4, dicycl)	 1,1-dimethyl-3-methylenecyclohexane

FIGURE 98. Chemical structures of the menaquinones found in *Smaragdicoccus* and *Nocardia*.

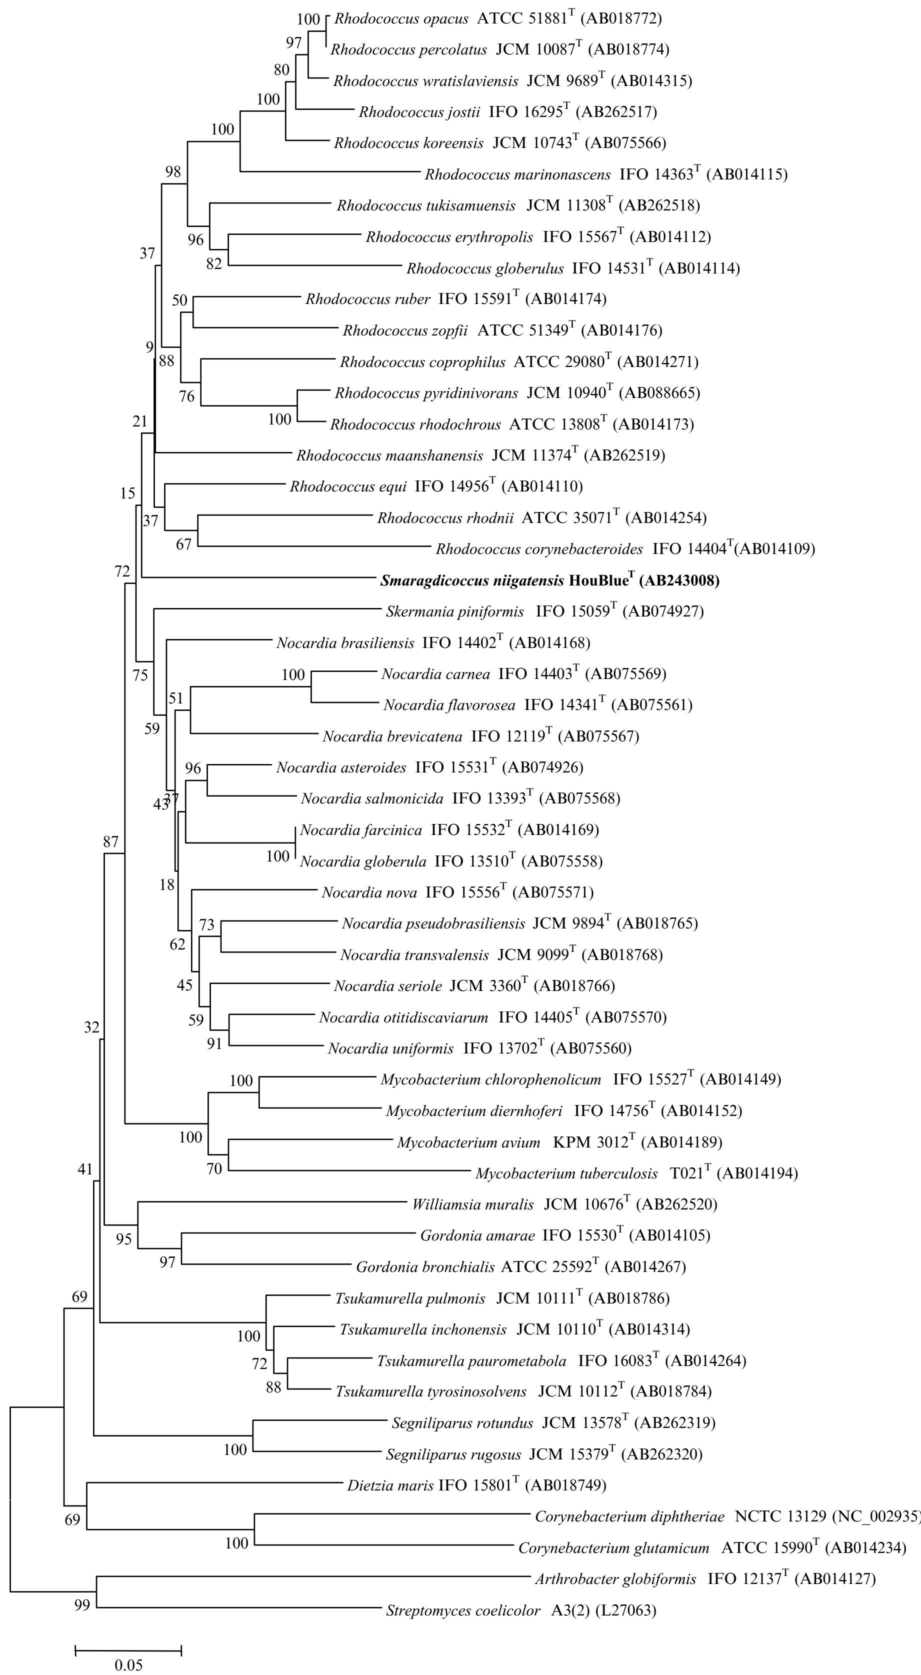

FIGURE 99. Neighbor-joining tree based on *gyrB* sequence comparisons showing the phylogenetic position of strain *Smaragdicoccus niigatensis* Hou_blue^{T}. 1260-nucleotide-long *gyrB* sequences were used for genetic distances calculation based on the Kimura two-parameter model. Bar, 5 nucleotide substitutions per 100 nucleotides.

List of species of the genus *Smaragdicoccus*

1. **Smaragdicoccus niigatensis** Adachi, Katsuta, Matsuda, Peng, Misawa, Shizuri, Kroppenstedt, Yokota and Kasai 2007, 300^{VP}

ni.i.ga.ten′sis. N.L. masc. adj. *niigatensis* of or belonging to Niigata Prefecture of Japan, the source of the soil from which the organism was isolated.

Coccoidal cells without branching (0.86 µm in diameter). The type strain Hou_blue^{T} utilizes the following carbon sources after 14 d of incubation at 30°C: D-fructose, D-glucose, sodium n-butyrate, and hexadecane. After prolonged incubation of 1 month, growth with sucrose is observed. Better growth is observed with 0.1% than 1% of these carbon sources. The following carbon sources were not used for growth: L-arabinose, *myo*-inositol, D-mannitol, L-rhamnose, raffinose, and D-xylose. Esterase activity (C4), esterase lipase (C8), lipase (C4), leucine arylamidase, naphthol-AS-BI-phosphohydrolase activities were detected by API ZYM enzyme assay.

The type strain was isolated from petroleum-contaminated soil at Nishiyama-cho, Niigata, Japan.

DNA G+C content (mol%): 63.7 (HPLC) for type strain.

Type strain: Hou_blue^{T}, CIP 109538, DSM 44881, IFM 10815, JCM 14666, MBIC 06267.

Sequence accession nos: AB243007 (16S rRNA gene) and (*gyrB*) AB243008.

Genus VII. **Williamsia** Kämpfer, Andersson, Rainey, Kroppenstedt and Salkinoja-Salonen 1999, 686^{VP}

Peter Kämpfer

Wil.li.am′si.a. N.L. fem. n. *Williamsia* named to honor Stanley Thomas Williams (1937–2004), a British microbiologist, for his numerous contributions to the taxonomy and ecology of actinomycetes.

Gram-stain-positive, non-sporing actinomycete which forms short rods. Aerobic and chemoheterotrophic. **The diagnostic amino acid** is ***meso*-diaminopimelic acid and the major cell-wall sugars are arabinose, galactose, mannose, and ribose.** Short chain mycolic acids are present (carbon chain length, C_{50}–C_{56}). The fatty acid pattern is mainly composed of straight-chain saturated and monounsaturated fatty acids. **Tuberculostearic acid is present in large amounts (>20% of the whole-cell fatty acids). The major polar lipids are phosphatidylethanolamine**, **phosphatidylinositol**, **phosphatidylglycerol, and diphosphatidylglycerol**. **Dihydrogenated menaquinone with nine isoprene units is the only isoprenologue**. On the basis of 16S rRNA gene sequence analysis, it is a member of the family *Gordoniaceae*.

DNA G+C content (mol%): 64–65 (HPLC).

Type species: **Williamsia muralis** Kämpfer, Andersson, Rainey, Kroppenstedt and Salkinoja-Salonen 1999, 686^{VP}.

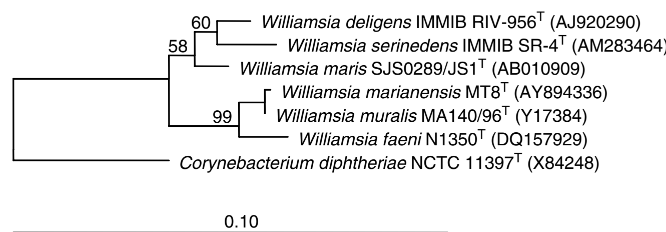

FIGURE 100. Phylogenetic analysis of *Williamsia* species based on 16S rRNA gene sequences available from the European Molecular Biology Laboratory data library (accession numbers in *parentheses*). The phylogenetic tree was constructed using the ARB software package (version December 2007; Ludwig et al., 2004) and the corresponding SILVA SSURef 95 database (release July 2008; Pruesse et al., 2007). Tree building was performed with the neighbor-joining method and without filters. Bootstrap values > 50% based on 1000 replications are listed as percentages at the branching points. Bar = 0.10 nucleotide substitutions per nucleotide position.

Further descriptive information

The genus *Williamsia* was proposed by Kämpfer et al. (1999) to accommodate an unusual mycolic-acid-containing actinomycete. Based on its mycolic acid profile, *Williamsia* occupies an intermediate position between *Rhodococcus* (mycolic acid chain length of 34–45 carbon atoms) and *Gordonia* (mycolic acid chain length 54–66 carbon atoms) (Kämpfer et al., 1999). The taxon currently contains six species with validly published names, *Williamsia deligens* (Yassin and Hupfer, 2006), *Williamsia faeni* (Jones et al., 2009), *Williamsia maris* (Stach et al., 2004), *Williamsia muralis* (Kämpfer et al., 1999), *Williamsia marianensis* (Pathom-aree et al., 2006), and *Williamsia serinedens* (Yassin et al., 2007b). Strains of these species were isolated from human blood, soil, meadow hay, deep-sea sediment, and indoor building materials. They form a distinct 16S rRNA group within the evolutionary radiation occupied by mycolic acid-containing actinomycetes, classified in the order *Corynebacteriales*, formerly suborder *Corynebacterineae* Stackebrandt et al. (1997). The range of 16S rRNA gene sequence similarities is 95.4–99.9%. A phylogenetic tree based on calculations with the maximum-likelihood algorithm is shown in Figure 100. Species of this genus are characterized by the presence of *meso*-A_2pm, arabinose, and galactose in whole-organism hydrolysates (wall chemotype IV *sensu* Lechevalier and Lechevalier, 1970), *N*-glycolyl muramic acid residues, dihydrogenated menaquinone with nine isoprene units as the sole isoprenologue, major proportions of straight chain, unsaturated, and tuberculostearic acids (fatty acid type 1b; (Kroppenstedt, 1985), phosphatidylethanol, diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol as major polar lipids (phospholipid type II *sensu* Lechevalier et al., 1977), and by mycolic acids that co-migrate with those of *Williamsia muralis* DSM 44343^{T} (Goodfellow and Maldonado,

2006; Pathom-aree et al., 2006; Yassin and Hupfer, 2006). The fatty acid profile is dominated by palmitic acid ($C_{16:0}$), hexadecenoic acid ($C_{16:1}$), oleic acid ($C_{18:1}$), and tuberculostearic acid (10-methyl octadecanoate). *Williamsia muralis* contains significant amounts of palmitoleic acid ($C_{16:1}$ *cis*9) whereas *Williamsia marianensis* has a fatty acid provisionally identified as hexadecenoic acid (Pathom-aree et al., 2006). In addition, *Williamsia muralis* contains a minor amount of $C_{16:1}$ *cis*11 (Kämpfer et al., 1999). The fatty acid profiles of *Williamsia marianensis* and *Williamsia muralis* are distinct from that found for the type strain of *Williamsia deligens* which was reported to contain only minor amounts of $C_{16:1}$ and significant quantities (40%) of the longer chain (C_{20}) saturated and unsaturated fatty acids (Yassin and Hupfer, 2006).

Enrichment and isolation procedures

No specific isolation medium has been described so far. Good growth occurs on nutrient rich media, like Brain heart Infusion agar, Tryptone Soy agar (TSA), and R2A agar (all from BBL Microbiology Systems), and glucose-yeast-extract agar (Gordon and Mihm, 1962) at 20–30°C.

Maintenance procedures

Williamsia cultures may be lyophilized by common procedures used for many bacteria (see also the chapter on *Gordonia*). In addition, cultures can be maintained by serial transfer on solid complex media. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Williamsia* from other genera

Williamsia may be distinguished form other genera in the order *Corynebacterales* by the cell-wall peptidoglycan, menaquinone type, colony pigmentation, DNA G+C content, and fatty acid composition (Table 29 in the chapter on the *Corynebacteriales*). Differentiation from the genus *Gordonia* is mainly based on 16S rRNA gene sequence analysis.

List of species of the genus *Williamsia*

1. **Williamsia muralis** Kämpfer, Andersson, Rainey, Kroppenstedt and Salkinoja-Salonen 1999, 686[VP]

mu.ra′lis. L. fem. adj. *muralis* pertaining or belonging to wall(s).

Coccoid cells without branching (0.4–0.5 µm in width, 0.6–1.4 µm in length). Smooth, saffron yellow colored colonies formed on TSB agar (BBL). The temperature range for growth is 10–37°C; the optimum is 30°C, and no growth is detected at 4°C or 41°C. Good growth occurs on Nutrient Agar (Difco), R2A agar (Difco), and TSA (BBL). Acetate, adonitol, citrate, D-fructose, fumarate, D-gluconate, D-mannitol, D-mannose, propionate, putrescine, sorbitol, sucrose, and pyruvate are utilized (after 4 d of incubation at 30°C) as sole sources of carbon; L-alanine, D-glucose, DL-3-hydroxybutyrate, and L-proline are utilized after 10 d of incubation. pNP-α-D-glucopyranoside and *bis*-pNP-phosphate are hydrolyzed. Further physiological characteristics are given in Table 49.

Source: indoor building material, Finland.

DNA G+C content (mol%): 64.8 (HPLC).

Type strain: MA 140–96, CIP 106979, DSM 44343, IFM 10085, JCM 10676, KCTC 9830.

Sequence accession no. (16S rRNA gene): Y17384.

2. **Williamsia deligens** Yassin and Hupfer 2006, 196[VP]

de. li′gens L. part. adj. *deligens* choosing, selecting, referring to the preference of carbon source.

Gram-stain-positive, rod and coccoid-like cells, are partially acid–alcohol-fast. Smooth, orange to orange-red pigmented colonies are found on agar media. Grows over the temperature range 22–37°C, but not at 42°C. Its mycolic acids are cleaved on pyrolysis to release $C_{16:0}$ and $C_{18:0}$ fatty acids as the major cleavage products. Hydrolyzes urea, but not esculin. Does not degrade adenine, casein, elastin, gelatin, guanine, hypoxanthine, testosterone, tyrosine, or xanthine. Utilizes acetate, 2,3-butandiol, citrate, glucose, mannitol, paraffin, sucrose, sorbitol, and trehalose as carbon sources. Does not utilize adipate, iso-amyl alcohol, cellobiose, gluconate, lactate, lactose, melezitose, 1,2-propandiol, or raffinose. Utilizes L-alanine, but not acetamide, arginine, gelatin, ornithine, proline, or serine as carbon and nitrogen sources. Further physiological characteristics are given in Table 49.

Source: human blood.

DNA G+C content (mol%): not determined.

Type strain: IMMIB RIV-956, CCUG 50873, DSM 44902, JCM 13662.

Sequence accession no. (16S rRNA gene): AJ920290.

3. **Williamsia faeni** Jones, Payne and Goodfellow 2010, 2550[VP]

fa.e′ni. L. n. *faenum* hay; L. gen. n. *faeni* of hay, referring to its isolation from a hay meadow.

Forms coccoid elements. Irregular, convex, matt yellow pink pigmented colonies are produced on glucose-yeast extract agar after incubation for 5 d at 28°C. Grows between 10 and 30°C, but not at 37°C. Hydrolyzes allantoin and urea, but not arbutin. DNA, RNA, starch, and uric acid are degraded, but not adenine, chitin, elastin, xanthine, or xylan. D(−)-Amygdalin, D(−)-arabinose, D(+)-arabitol, arbutin, D(−)-fructose, D(−)-fucose, D(−)-glucose, inulin, D(+)-lactose, D(+)-mannose, D(+)-melibiose, α-methyl-D-glucoside, D(−)-ribose, and D(+)-turanose are used as sole carbon sources for energy and growth, but not dulcitol or salicin (all at 1%, w/v); butan-1,3-diol, butan-1,4-diol, butan-1-ol, butan-2,3-diol, ethanol, propan-1-ol, and propan-2-ol are also used as sole carbon sources (all at 1%, v/v); with *iso*-amyl alcohol, benzoic acid, fumaric acid, glycerol, glycogen, L-(+)-lactic acid, L-malic acid, oleic acid, propanoic acid, pyruvic acid, sodium acetate, sodium *n*-butyrate, L-(+)-tartaric acid, valeric acid, and xylitol used as carbon sources (all at 0.1%, w/v),

[a] Results for the reference strains taken from Kämpfer et al. (1999), Jones et al. (2009), Stach et al. (2004), Yassin and Hupfer (2006), and Pathom-aree et al. (2006).

but not adipic acid, citric acid, glutaric acid, malonic acid, D-mandelic acid, oxalic acid, sebacic acid, suberic acid, or succinic acid. Acetamide, L-alanine, L-aminobutyl, L-arginine, L-gelatin, D-gluconic acid, L-glycine, histidine, L-leucine, DL-methionine, monoethanolamine, DL-norleucine, L-norvaline, DL-phenylalanine, L-proline, serine, uric acid, urea, and L-valine are used as sole carbon and nitrogen sources (all at 0.1%, w/v), but not L-cysteine, L-glutamic acid, L-isoleucine, or L-ornithine. The fatty acid profile includes major amounts of hexadecanoic ($C_{16:0}$, 21% of total), monosaturated octadecanoic ($C_{18:1}$, 15%), tridecanoic ($C_{13:0}$, 11%), tuberculostearic (10-methyl octadecanoate [10-methyl $C_{18:0}$], 8%) and octadecanoic ($C_{18:0}$, 7%) acids; minor components include tetradecanoic ($C_{14:0}$), pentadecanoic ($C_{15:0}$), *iso*-hexadecanoic ($C_{16:0}$ iso), and eicosanoic acids ($C_{20:0}$). Further physiological characteristics are given in Table 49.

Source: a hay meadow plot at Cockle Park Experimental Farm, Northumberland, UK.

DNA G+C content (mol%): not determined.

Type strain: N1350, DSM 45372, NCIMB 15474, NRRL B-24794.

Sequence accession no. (16S rRNA gene): DQ157929.

4. **Williamsia marianensis** Pathom-aree, Nogi, Sutcliffe, Ward, Horikoshi, Bull and Goodfellow 2006, 1125[VP]

ma.ri.an′ensis. N.L. fem. adj. *marianensis* of or pertaining to the Mariana Trench, the source of the isolate.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast, non-motile actinomycete which forms short rods and coccoid-like elements. Round, entire, convex, orange colonies with smooth matt surfaces are formed on glucose-yeast extract agar after 5 d incubation at 28°C. Good growth occurs on

TSA between 4 and 30°C, with an optimum temperature around 28°C. Neither arbutin nor esculin are hydrolyzed. Casein, cellulose, hypoxanthine, starch, and uric acid are degraded, but not gelatin, guanine, Tween 80, L-tyrosine, or xanthine. D-Fructose, D-mannitol, D-mannose, D-sucrose, D-sorbitol, and xylitol are used as sole carbon sources for energy and growth, but not L-arabitol, D-cellobiose, dextran, dextrin, D-glycerol, glycogen, D-melezitose, D-raffinose, D-salicin, or L-sorbose. Further physiological characteristics are given in Table 49.

Source: deep-sea sediment taken from the Mariana Trench.

DNA G+C content (mol%): 65.4 (HPLC).

Type strain: MT8, DSM 44944, JCM 14345, NCIMB 14085.

Sequence accession no. (16S rRNA gene): AY894336.

5. **Williamsia maris** Stach, Maldonado, Ward, Bull and Goodfellow 2004, 193[VP]

ma′ris. L. neut. n. *mare*, the sea; L. gen. n. *maris* of the sea.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast, nonmotile actinomycete which forms short rods and coccoid-like elements. Round, convex, orange colonies are formed on glucose-yeast extract agar after 5 d incubation at 28°C; the colonies assume a pinkish hue after incubation for 5–10 d. Good growth on modified Bennett's and Tryptic Soy agars. Growth occurs between 10 and 37°C, with an optimum around 28°C. Utilizes glycerol, glycogen, *meso*-inositol, L-rhamnose, L-sorbose, and D-xylose as sole sources of carbon for energy and growth, but not D-arabitol, L-arabitol, dextran, dextrin, dulcitol, D-galactose, inulin, α-lactose, D-melezitose, α-D-methyl-glucopyranoside, D-raffinose, D-ribose, D-salicin, xylan, or xylitol. Further physiological characteristics are given in Table 49.

Source: sediment collected from the Sea of Japan at a depth of 289 m.

DNA G+C content (mol%): not determined.

Type strain: SJS0289/JS1, DSM 44693, JCM 12070, KCTC 9945, NCIMB 13945.

Sequence accession no. (16S rRNA gene): AB010909.

6. **Williamsia serinedens** Yassin, Young, Lai, Hupfer, Arun, Shen, Rekha and Ho 2007b, 560[VP]

se.ri.ne′dens. N.L. n. *serinum* serine; L. part. pres. *edens* eating; N.L. part. adj. *serinedens* eating serine.

Forms smooth, orange to orange-red pigmented colonies on agar media. Cells are Gram-stain-positive rods and are non-acid–alcohol-fast. Grows at 22–30°C, but not at higher temperatures. Contains the salient chemotaxonomic characteristics of the genus *Williamsia*. Its mycolic acids were cleaved on pyrolysis to release $C_{16:0}$ and $C_{18:0}$ fatty acids as the major products. The fatty acid profile consists mainly of straight-chain saturated, unsaturated, and 10-methyl branched fatty acids. Hydrolyzes gelatin and urea but not adenine, casein, elastin, esculin, guanine, hypoxanthine, testosterone, tyrosine, or xanthine. Assimilates acetate, adonitol, L-arabinose, 2,3-butandiol, citrate, *meso*-erythritol, galactose, glucose, *p*-hydroxybenzoate, lactate, maltose, mannitol, paraffin, 1,2-propandiol, sucrose, sorbitol, trehalose, and xylose as carbon sources, but not adipate, isoamyl alcohol, cellobiose, gluconate, *m*-hydroxybenzoate, *myo*-inositol, lactose, melezitose, raffinose, or rhamnose. Utilizes acetamide, L-alanine, and serine as simultaneous carbon and nitrogen sources, but not arginine, gelatin, ornithine, or proline.

Source (type strain): an oil-contaminated soil sample in Chyai County, Taiwan.

DNA G+C content (mol%): not determined.

Type strain: IMMIB SR-4, DSM 45037, CCUG 53151, JCM 14883.

Sequence accession no. (16S rRNA gene): AM283464.

Family V. **Segniliparaceae** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles 2005, 1621[VP] emend. Zhi, Li and Stackebrandt 2009, 595

W. Ray Butler

Seg.ni.li.pa.ra.ce′a.e. N.L. masc. n. *Segniliparus* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Segniliparaceae* the *Segniliparus* family.

Aerobic, acid–alcohol-fast, nonmotile, nonsporeforming, rod-shaped cells (0.4 µm in diameter). Does not show branching or produce an aerial mycelium. Strains form smooth and rough colony variants. **Mesophilic**, **with an optimum growth temperature of 33°C**. Visible growth in 3–4 d. **Branched β-hydroxy fatty acid in the cell wall is of an alpha-chemical mycolic acid structural type**. **The principal diamino acid of the peptidoglycan is *meso*-diaminopimelic acid**. Contains tuberculostearic acid. Found in the environment. The family is represented by a single genus, *Segniliparus.*

DNA G+C content (mol%): 68–72.

Type genus: **Segniliparus** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles 2005, 1621[VP].

Genus I. **Segniliparus** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles 2005, 1621[VP]

W. Ray Butler

Seg.ni.li.pa′rus. L. adj. *segnis* slow; Gr. adj. *liparos* fatty; N.L. masc. n.*Segniliparus* the slow fatty one, the one with slow fats, to indicate the possession of slowly reacting fatty acids, i.e. late-eluting mycolic acids detected with HPLC.

Aerobic, acid–alcohol-fast, nonmotile, actinomycete which forms straight, short to long rods. Cocci are not formed and branching is not evident. Does not form pili or flagella. Grows on media designed for the genus *Mycobacterium*, but not on heart infusion agar. Growth on chocolate agar is embedded in the surface and is mucoid-like. Division is by binary fission. **Cells contain non-oxygenated, non-polar, alpha-mycolic acids**. Growth occurs in 3–4 d at 22°C but is reduced at 45°C and at pH 6.6. **Optimal growth temperature is 33°C**. Colonies are nonpigmented, nonphotochromogenic, and odorless.

DNA G+C content (mol%): 68–72 (T_m).

Type species: **Segniliparus rotundus** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles, 2005, 1622[VP].

Further descriptive information

Cells are rod shaped and of variable lengths (1.0–1.3 or 0.76–1.93 × 0.4 µm). The variety in rod length is responsible for the distinctive colony formation and appears to be species specific. Cells grow aerobically in Middlebrook and Cohn 7H9 broth with ADC enrichment, and in 7H10 and 7H11 agars with OADC enrichment. Grows on TGY agar at 25, 35, and 45°C and shows retarded, if any, growth on heart infusion agar. Colonies shine and glisten under the light microscope.

The peptidoglycan contains mycolic acids and *meso*-diaminopimelic acid. 10-Methyloctadecanoic acid (tuberculostearic acid) is part of the fatty acid profile, a characteristic of the order *Actinomycetales.* The presence of α-branched, β-hydroxy fatty acids (mycolic acids) places strains of the genus *Segniliparus* with the other mycolic acid-containing genera. The mycolic acids have long carbon chains and lack oxygen functions other than those of the hydroxyl group. Mycolic acid chemical functional groups are representative of a series of non-oxygenated, nonpolar mycolic acids designated α- and α′-mycolic acids. The α′-mycolic acids are indicative of the family *Segniliparaceae* and appear longer than the C_{90} carbon mycolic acids present in mycobacteria. Mass spectrometry confirms that a C_{24} fatty acid is derived from pyrolysis of the β-hydroxy, acyl side-chain of mycolic acids at 300°C, similar to some species of *Mycobacterium.*

High performance liquid chromatography (HPLC) of ρ-bromophenacyl esters of mycolic acids used to identify species in the genus *Mycobacterium* can be used to readily detect species in the genus *Segniliparus* (Butler et al., 1986). Many extremely long, α′-structural types of mycolic acids present a distinctive HPLC reference pattern (Butler et al., 2005). The late co-emergence of nonpolar, α′-mycolic acids as shoulder peaks with a nonpolar high-molecular-mass, 110 carbon-standard in the HPLC process, is an exclusive characteristic of the genus *Segniliparus.* Similar chemotaxonomic characteristics are noteworthy for rapidly growing *Mycobacterium* and for some species of the genus *Tsukamurella.*

Characteristic biochemical patterns of the species of the genus *Segniliparus* are given in Table 50. In addition, strains fail to hydrolyze acetamide, adenine, casein, esculin, hypoxanthine, tyrosine, and xanthine. L-Arabinose, cellobiose, citrate, dulcitol, iso-erythritol, galactose, iso-*myo*-inositol, lactose, mannose, melibiose, raffinose, L-rhamnose, salicin, and sodium citrate are used as sole carbon sources. Does not exhibit alkaline phosphatase, β-galactosidase, β-glucuronidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, or pyrrolidonyl arylamidase activity.

Clinical strains have been isolated from non-sterile human specimens including sputum and nasal region and bronchial washings. MIC susceptibility breakpoints for antibacterial and antituberculosis drugs are determined after incubation of strains for 3 d at 30°C. Standardized testing conditions for the genus are unknown, hence performance standards for nontuberculosus mycobacteria and *Nocardia* are utilized

TABLE 50. Characteristics differentiating species of the genus *Segniliparus*[a]

Characteristic	*S. rotundus*	*S. rugosus*
Cell morphology	Rods of similar length	Rods of variable length
Cell length	1.0–1.3 × 0.4 μm	0.76–1.93 × 0.4 μm
Colony morphology (texture)	Smooth (dense)	Rough-wrinkled (creamy)
α-Mycolic acids	+	+
Acid–alcohol-fast	+	+
Complete growth swirl on MacConkey agar	−	+
Produces pinkish diffusible pigment >4 weeks	−	v
Growth on sodium chloride after 7/14 d	−/+	+/+
Develop >45 mm bubbles in catalase test	+	+
Growth in lysozyme	−	v
Arylsulfatase activity after 3/14 d	+/+	v/+
Tween hydrolysis	+	v
Tween opacity	v	+
Nitrate reduction	−	v
Tellurite reduction	−	+
Nitrate reduction	−	v
Iron uptake	−	v
Niacin production	−	−
Urea hydrolysis	+	+
Carbon used/acid produced:

Trehalose	+/+	+/+
Presence of:		
β-Glucosidase	+	+
Pyrazinamidase	+	+

[a]Symbols: +, positive in most strains; −, negative in most strains; v, variable in different strains.

(National Committee on Clinical Laboratory Standards, 2003). Adequate growth requires a substitution of 7H9 broth for the recommended cation-adjusted Mueller–Hinton broth (Clinical Laboratory Standards Institute, 2006). Generally, both species are resistant to amikacin, clarithromycin, ethambutol, and tobramycin, but susceptible to imipenum, rifabutin, sulfamethoxazole, and trimethoprim-sulfamethoxazole. However, consideration must be given to drug results as efficacies may be ambiguous for the test conditions.

Segniliparus rugosus presents in infections of lungs of cystic fibrosis patients, although the comprehensive role in the disease is unknown. However, physicians consider the isolates to be opportunistic acid-fast pathogens and not colonization bacteria due to multiple isolations from sputum and bronchial washings, and to a rapidly progressive disease that is not typical of cystic fibrosis. Clinical strains analyzed with multilocus enzyme electrophoresis reveal dissimilar electrophoretic types indicative of environment contact and not human transmission. Misidentifications of clinical isolates occur as *Mycobacterium abscessus*, *Mycobacterium chelonae*, and uncharacterized nontuberculosus mycobacteria. Accurate species identification is made by comparison to 16S rRNA gene sequences deposited in GenBank for *Segniliparus* or by HPLC analysis of mycolic acids. The family consists of a single genus, *Segniliparus*, represented by two species, *Segniliparus rotundus* and *Segniliparus rugosus*. *Segniliparus rugosus* is the only reported species associated with disease.

Enrichment and isolation procedures

The methods employed for the isolation and growth of the *Segniliparus* species are the same as those used for the genus *Mycobacterium* (Kent and Kubica, 1985). Comprehensive growth requirements are undetermined and strains have been nonviable upon subculture with mycobacteria media.

Maintenance procedures

Stock cultures of *Segniliparus* can be stored in Middlebrook and Cohn 7H9 broth with added ADC enrichment at −70°C. Cultures have been kept in trypticase soy broth with 15% glycerol at −70°C. Recovery is in 7H9 broth or on 7H11 agar at 33–37°C. Subcultures have been maintained on LJ, 7H9, 7H10, and 7H11. Lyophilized cultures are preserved at −70°C.

Taxonomic comments

The taxonomic circumscription of the genus *Segniliparus* is supported by two publications, and a reassessment of its phylogenetic position is likely as more genetic data become available. The chemotaxonomic characteristic of α-, α′-mycolic acids analyzed by HPLC distinguishes the genus from other mycolic acid containing genera, and the longer carbon length suggests an ancestral evolutionary position within mycolic acid-containing taxa. 16S rRNA gene based comparisons confirm a close association between *Segniliparus* strains and provide genetic evidence for the circumscription of the genus. However, other genetic intra-relationships confirmed with multilocus enzyme electrophoresis typing with cellular enzymes reveals the separation of two strains with identical 16S rRNA gene sequences within the species *Segniliparus rugosus*. The different electrophoretic types suggest an uncharacterized species and demonstrate taxa delineation issues.

Evolutionary tree construction based on 16S rRNA gene sequences shows a distinct lineage within other genera containing mycolic acids. A 16S rRNA gene similarity of 98.9% (15 bp difference) between the type strains of the species is in line with a DNA–DNA hybridization (hydroxyapatite method with an optimum reassociation temperature of 70°C) value of <28% and underpins the separation of the two *Segniliparus* species. An overall 16S rRNA genetic similarity for gene sequences deposited in GenBank is 94.5% for *Segniliparus rotundus* and 94.8% for *Segniliparus rugosus* with a speculated genetic neighbor *Rhodococcus equi* ATCC 6939^{T}; values correspond to 78 and 79 bp differences, respectively. These divergent values also highlight the distinctiveness of the genus, but phylogenetic tree construction places *Segniliparus* in an illogical association with *Rhodococcus equi*. This association is not

supported by a DNA–DNA hybridization value of 2% with the *Rhodococcus equi* strain. Also, the absence of the *Rhodococcus equi*-specific cholesterol oxidase virulence gene is inconclusive for *Rhodococcus equi*.

The uncertainty of the genetic relationships of the genus *Segniliparus* is supported by the HPLC presentation of unique long chain mycolic acids and GLC detection of $C_{10:0}$ fatty acids, neither of which is found in *Rhodococcus equi*. These results suggest an apparent treeing artifact resulting from insufficient taxonomic data with respect to these taxa. The hypothetical evolutionary history position will likely vary when other representatives of the genus are examined or when interrelated families are discovered. This subject remains unsettled and will receive consideration as additional information is discovered for strains of the genus *Segniliparus*.

Differentiation of the genus *Segniliparus* from other genera

Classical biochemical differentiation of the genus *Segniliparus* is inadequate. The acid–alcohol-fast staining nature of *Segniliparus* strains immediately eliminates bacteria that lack this characteristic and associates strains with the suprageneric assemblage of mycolic acid-containing actinomycetes, namely the genera *Corynebacterium*, *Dietzia*, *Gordonia*, *Millisia*, *Mycobacterium*, *Nocardia*, *Rhodococcus*, *Skermania*, *Smaragdicoccus*, *Tsukamurella*, and *Williamsia*. HPLC chemotaxonomic analysis of mycolic acids provides a reliable separation of mycolic acid-containing actinomycetes. Comparative analysis of the first 500 bp or of the almost complete 16S rRNA gene easily differentiates the genus *Segniliparus* by comparison to reference sequences deposited in GenBank for other mycolic containing taxa.

List of species of the genus *Segniliparus*

1. **Segniliparus rotundus** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles 2005, 1622[VP]

ro.tun′dus. L. masc. adj. *rotundus* rounded, referring to the smooth, round-domed colony forms.

Characteristics are the same as those described for the genus. Cells are of a similar size (1.0–1.3 × 0.4 μm). During cell division, rods are equally divided, producing V-forms. Cells distribute easily in broth medium. Short rods produce dense, smooth, round-domed colonies. Colonies are opaque, colorless (whitish), and can be pushed intact across the agar surface.

DNA G+C content (mol%): 68 (T_m).

Type strain: CDC 1076, ATCC BAA-972, CIP 108378, JCM 13578.

Sequence accession no. (16S rRNA gene): AY608918.

Further comments: an additional strain is ATCC BAA-973 = CIP 108379.

2. **Segniliparus rugosus** Butler, Floyd, Brown, Toney, Daneshvar, Cooksey, Carr, Steigerwalt and Charles 2005, 1622[VP]

ru.go′sus. L. masc. adj. *rugosus* wrinkled, in reference to the wrinkled-rough colony morphology.

Characteristics are the same as those described for the genus. Cells are 0.76–1.93 × 0.4 μm. Unequal cell division of the longer cells often results in the disproportional length of new cells. Cells aggregate in broth medium. Colony centers have a wrinkled-rough texture composed of older cell growth. The colony border is smooth with undulating edges, representative of new cell growth. Young colonies are colorless with a creamy texture and smear when disturbed. Colonies of the type strain >4 weeks old develop a pinkish, diffusible-pigment on 7H11 at <33°C, but produce greening on LJ. Infrequent colony conversions to smooth forms are seen after >4 week growth. Strains found thus far occur in non-sterile human clinical specimens.

DNA G+C content (mol%): 72 (T_m).

Type strain: CDC 945, ATCC BAA-974, CIP 108380, JCM 13579.

Sequence accession no. (16S rRNA gene): AY608920.

Further comments: an additional strain is ATCC BAA-975 = CIP 108381.

Family VI. **Tsukamurellaceae** Rainey, Ward-Rainey and Stackebrandt 1997, 486[VP]

Michael Goodfellow

Tsu.ka.mu.rel.la.ce′a.e. N.L. fem. n. *Tsukamurella* the type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Tsukamurellaceae* the *Tsukamurella* family.

The family *Tsukamurellaceae* Rainey et al. 1997 was proposed for members of the genus *Tsukamurella* as these organisms showed a distinctive pattern of 16S rRNA signatures, namely nucleotides at positions 70:98 (U–A), 293:304 (G–U), 307 (C), 631 (C), 661:744 (G–C), 824:876 (U–A), 825:875 (A–U), 843 (C), 1007:1022 (G–U), and 1122:1151 (A–U).

Type genus: **Tsukamurella** Collins, Smida, Dorsch and Stackebrandt 1988, 387[VP].

Genus I. **Tsukamurella** Collins, Smida, Dorsch and Stackebrandt 1988, 387[VP]

Michael Goodfellow and Yashawant Kumar

Tsu.ka.mu.rel′la. N.L. fem. dim. n. *Tsukamurella* named in honor of Michio Tsukamura, a celebrated Japanese microbiologist.

Aerobic, Gram-stain-positive, partially acid–alcohol-fast, nonmotile, nonsporeforming actinomycetes. **Straight to slightly curved rods occur in pairs or in masses though coccobacillary forms are also present.** Cells may give a pseudomycelial appearance. Chemoorganotrophic with an oxidative metabolism. Rough, dry, flat, or folded colonies form on Lowenstein-Jensen medium and on brain heart infusion agar. Colonies are normally white or yellow to tan or beige. **Aerial hyphae are not formed.** Catalase–positive, arylsulfatase–negative, and lysozyme–resistant.

Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid, arabinose, and galactose. The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-glycolated. **Cells contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as predominant polar lipids, major amounts of straight chain saturated, unsaturated, and 10-methyloctadecanoic (tuberculostearic) fatty acids, and unsaturated menaquinones with nine isoprene units. Mycolic acids have 62–78 carbon atoms and 1–7 double bonds. The fatty acid esters released on pyrolysis mass spectrometry of mycolic acid esters have 22–26 carbon atoms.** The phylogenetic position of the family *Tsukamurellaceae*, as determined by 16S rRNA gene sequence analysis, is in the order *Corynebacteriales*.

Found in a diverse range of aquatic and terrestrial habitats, notably in activated sewage sludge foam and clinical material.

DNA G+C content (mol%): 68–78.

Type species: **Tsukamurella paurometabola** corrig. (Steinhaus 1941) Collins, Smida, Dorsch and Stackebrandt 1988, 387[VP] (*Corynebacterium paurometabolum* Steinhaus 1941, 783).

Further descriptive information

Phylogeny. The nine species of the genus *Tsukamurella* form a well-delineated clade within the evolutionary radiation occupied by genera classified in the order *Corynebacteriales* (Figure 101). The type strains of these taxa share identical or almost identical 16S rRNA gene similarity values but can be distinguished using DNA–DNA relatedness, ribotyping, and phenotypic data (Kattar et al., 2001; Nam et al., 2003a; Olson et al., 2007).

Cell morphology. Most tsukamurellae form straight to slightly curved rods (0.5–0.8 × 1.0–5.0 µm) that occur singly, in pairs, or in masses. Coccobacillary forms occur. In *Tsukamurella pulmonis* and *Tsukamurella tyrosinosolvens*, cells tend to be long rods which in later stages of growth fragment into three parts that separate and grow as independent rods (Yassin et al., 1996, 1997). Neither aerial hyphae, capsules, spores, nor true branching have been observed.

Cell envelope composition. Tsukamurellae have (a) a peptidoglycan composed of *N*-acetylglucosamine, D-alanine, L-alanine, and D-glutamic acid with *meso*-diaminopimelic acid (*meso*-A_2pm) as the diamino acid, and muramic acid in the *N*-glycolated form; (b) arabinose and galactose as diagnostic wall sugars (i.e. whole-organism sugar pattern type A *sensu* Lechevalier and Lechevalier, 1970), (c) a phospholipid pattern consisting of diphosphatidylglycerol, phosphatidylethanolamine (taxonomically significant phospholipid), phosphatidylinositol, and phosphatidylinositol mannosides (i.e. phospholipid pattern type II *sensu* Lechevalier et al., (1981, 1977), (d) a fatty acid profile consisting of major amounts of straight chain, unsaturated, and tuberculostearic acids (i.e. a type IV fatty acid pattern *sensu* Lechevalier et al., 1977), (e) mycolic acids with 62–78 carbon atoms (Collins and Jones, 1982; Collins et al., 1988; Olson et al., 2007), and (f) unsaturated menaquinones with nine isoprene units as the predominant isoprenologue (Collins et al., 1988; Nam, 2004).

Two dimensional thin-layer chromatography of whole-organism acid and alkaline methanolysates of *Tsukamurella* strains give a characteristic mycolic acid pattern consisting of α- and α′ mycolates in addition to the nonhydroxylated fatty acid spot (Yassin et al., 1995, 1996, 1997). The predominant fatty acids are hexadecanoic ($C_{16:0}$, 25–40%), oleic ($C_{18:1}$ ω9, 24–35%), and tuberculostearic ($C_{18:0}$ 10 methyl, 8–18%) acids (Nam et al., 2003a).

The type strain, *Tsukamurella paurometabola*, contains a new lipoarabinomannan variant, designated Tpa LAM, which shows pro-inflammatory activity when tested with either human or murine monocyte/macrophage cell lines (Gibson et al., 2004). This induction was completely annulled in the presence of an

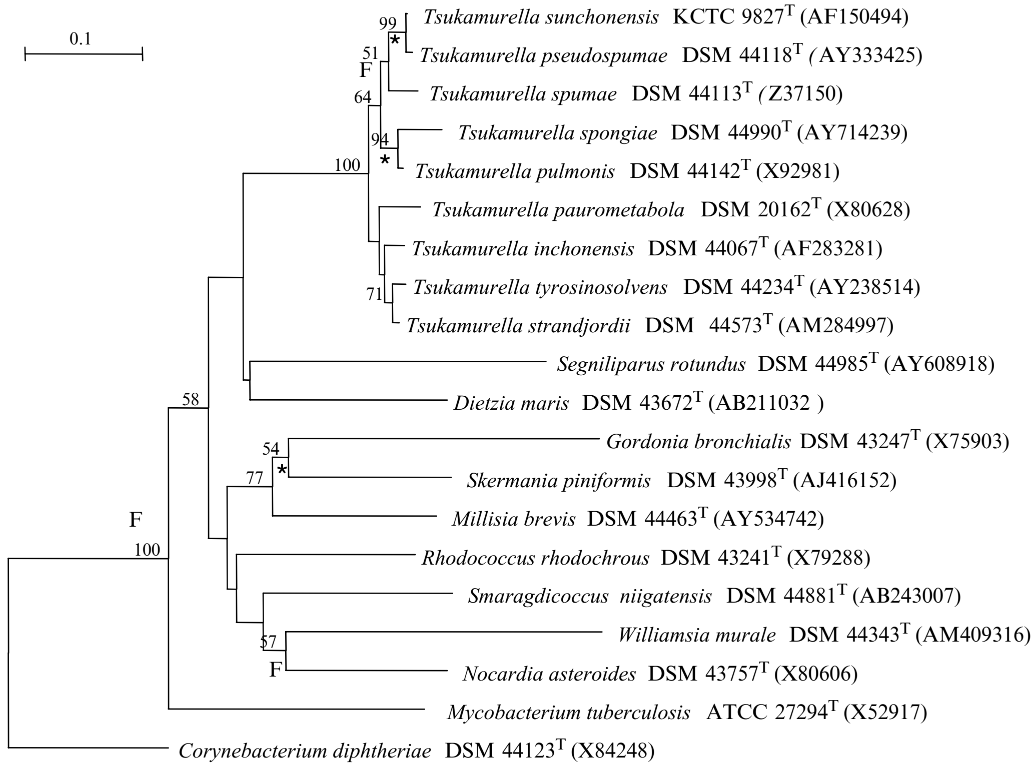

FIGURE 101. 16S rRNA neighbor-joining tree showing relationships between *Tsukamurella* species and representatives of other mycolic acid-containing genera classified in the order *Corynebacteriales*. Asterisks indicate branches of the tree that were also found using the least-squares and maximum-parsimony tree-making algorithms. F indicates a branch that was also recovered using the least-squares method. The numbers at the nodes indicate the level of bootstrap support derived from a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. The bar indicates 0.1 substitutions per nucleotide position.

anti-toll-like receptor-2 (TLR-2) antibody which suggests that TLR-2 participates in the mediation of the pro-inflammatory cytokine tumor necrosis factor (TNF)-α in response to Tpa LAM. The lipomannan core of Tpa LAM is the primary moiety responsible for the observed TNF-α-inducing activity. The predominant motifs of the major cell wall arabinogalactan antigens of the type species *Tsukamurella paurometabola* have been structurally elucidated (Tropis et al., 2005).

A prospective member of a novel *Tsukamurella* species produced novel glycolipids (biosurfactants) when grown on sunflower oil as the sole carbon source (Vollbrecht et al., 1998). The glycolipids showed good surface–active behavior, and had antimicrobial properties. Dörner et al. (2004) detected a cation-specific channel (TipA) in the cell wall of a *Tsukamurella inchonensis* strain and went on to show that the gene of the channel-forming protein was identical to *mspA* of *Mycobacterium smegmatis* and *mppA* of *Mycobacterium phlei*.

Colony morphology. Rough, dry, flat, or folded, creamy white or yellow to tan or beige colonies are formed on Lowenstein-Jensen medium and brain heart infusion agar. Large colonies (3–5 mm) are produced on Middlebrook 7H11 and tryptic soy agar (Kattar et al., 2001). The colonies of *Tsukamurella inchonensis*, *Tsukamurella pulmonis*, *Tsukamurella strandjordii*, and *Tsukamurella tyrosinosolvens* are dry, rough, velvety, and flat but with a slightly raised center, and show a variety of colors. Those of *Tsukamurella inchonensis* and *Tsukamurella strandjordii* are yellow to orange whereas those of *Tsukamurella pulmonis* and *Tsukamurella tyrosinosolvens* are tan and buff. The type strain of *Tsukamurella paurometabola* produces smooth, creamy colonies with entire edges that have a distinctive fried egg appearance. *Tsukamurella spongiae* forms dry, matt, cream colonies with irregular spreading margins and raised, wrinkled, rough centers on marine agar (Olson et al., 2007). *Tsukamurella sunchonensis* forms rough, orange colonies (Seong et al., 2003).

Nutrition and growth conditions. Tsukamurellae grow well on most standard media, including modified Bennett's (Jones, 1949), brain heart infusion (Difco), modified Sauton's supplemented with thiamine (Mordarska et al., 1972), and nutrient (Oxoid) agars, and on Lowenstein-Jensen slants (BBL). Good growth occurs at 25–37°C.

Metabolism. Little is known about the metabolic properties of tsukamurellae though they are able to degrade a number of organic substrates and use a broad range of compounds as sole carbon and carbon and nitrogen sources (Erdlenbruch et al., 2001, Goodfellow et al., 1991, 1996; Nam et al., 2003a, 2004; Olson et al., 2007). They can also cleave a range of 7-amino-4-methylcoumarin (7-AMC-) and 4-methylumbelliferone (4MU-) conjugated fluorogenic substrates (Goodfellow et al., 1991; Nam et al., 2004). The results of a comprehensive numerical

taxonomic study based on such properties underpin the taxonomic integrity of *Tsukamurella* species (Nam, 2004).

Most, if not all, *Tsukamurella* strains degrade starch, Tweens 20, 40, 60, and 80, and uric acid, but not adenine, casein, elastin, keratin, guanine, testosterone, xanthine, or xylan; they utilize galactose, gentiobiose, glucose, *meso*-inositol, lactose, mannose, raffinose, rhamnose, ribose, sucrose, trehalose, turanose, xylitol, and xylose as sole carbon sources, but do not use adonitol or rhamnose; they use acetamide, alanine, asparagine, proline, and serine as sole carbon and nitrogen sources (Nam, 2004, 2003a), and cleave L-alanyl-7-AMC, benzyloxycarbonyl–glycyl–prolyl-7-AMC, L-glutamic acid-7-AMC, L-leucyl-7-AMC, lysyl-7-AMC, L-proline-7-AMC-L-phenylalanyl-7-AMC, 4MU-acetate, 4MU-butyrate, and 4MU-α-D-glucoside (Nam et al., 2003a). The type strains of *Tsukamurella inchonensis* and *Tsukamurella paurometabola*, like representatives of the genus *Corynebacterium*, produce similar polyamine patterns with spermadine as the predominant component (Altenburger et al., 1997).

Antibiotic sensitivity. The few comparative antibiotic sensitivity studies that have been carried out on *Tsukamurella* strains have been driven mainly by taxonomic considerations. *Tsukamurella* strains are resistant (μg/ml) to clindamycin (2), colistin (25), cotrimoxazole (25), fusidic acid (10), nalidixic acid (5), novobiocin (5), and penicillin (1 IU), but are sensitive to ciprofloxazine (5). Several antibiotic combinations have been proposed for the treatment of infections caused by *Tsukamurella* strains. The combination of a β-lactam and an aminoglycoside together with the removal of medical devices, would appear to be the treatment of choice (Alcaide et al., 2004), but optimal management is uncertain and should be based on susceptibility testing (Chong et al., 1997; Schwartz et al., 2002). A *Tsukamurella paurometabola* strain, like representatives of other mycolic acid-containing taxa, was found to be susceptible to imidazole antifungal drugs (Dabbs et al., 2003).

Pathogenicity. Information on human infections attributed to tsukamurellae is sparse and tends to be from reports on single strain histories (Rey et al., 1997). These suggest that *Tsukamurella* infections are sporadic, community acquired, and nosocomial in origin. However, infections caused by tsukamurellae may go unrecorded as the offending strains may be either missed or misidentified in diagnostic laboratories (Alcaide et al., 2004; Stanley et al., 2006). The most common clinical presentations caused by *Tsukamurella* species in humans are cutaneous infections, meningitis, pulmonary, and device related infections including catheter-related bacteremia, especially of the central venous catheter (Lai, 1993; Maertens et al., 1998; Schwartz et al., 2002; Sheridan et al., 2003). *Tsukamurella* strains have been shown to cause peritonitis associated with continuous ambulatory peritoneal dialysis (Shaer and Gadegbeku, 2001), a knee prosthesis infection (Larkin et al., 1999), and cavitary pneumonia in an AIDS patient (Alcaide et al., 2004). Most *Tsukamurella* infections occur in immunocompromised hosts, particularly those with underlying chronic lung disease. Most of the cases reported in the literature have been attributed to *Tsukamurella paurometabola*.

The first documented case of a *Tsukamurella* infection was made by Tsukamura and Kawakami (1982) who repeatedly isolated a *Tsukamurella paurometabola* strain from a lung infection in a nonimmunocompromised 50-year-old man. Subsequently, *Tsukamurella paurometabola* strains have been associated with cases of bacteremia (Jones et al., 1994; Lai, 1993; Shapiro et al., 1992), a chest disorder (Osoagbaka, 1989), lethal meningitis (Prinz et al., 1985), severe gangrenous tendosynovitis with multiple subcutaneous abscesses (Tsukamura et al., 1988), and with a cutaneous infection (Granel et al., 1996). Cases of catheter-related bacteremia have been attributed to *Tsukamurella pulmonis* and *Tsukamurella tyrosinosolvens* (Elshibly et al., 2005; Maertens et al., 1998; Schwartz et al., 2002; Sheridan et al., 2003). Members of these taxa have also been reported to cause lung infections, as has *Tsukamurella inchonensis* (Yassin et al., 1995, 1996, 1997). *Tsukamurella strandjordii* was isolated from blood cultures of a child with acute mycelogenous leukemia (Kattar et al., 2001). *Tsukamurella* strains with phenotypic properties similar to those of *Tsukamurella pulmonis* and *Tsukamurella tyrosinosolvens* have been considered to cause conjunctivitis (Woo et al., 2003). Similarly, a *Tsukamurella* strain has been implicated as the causal agent of an implantable cardioverter-defibrillator infection (Almehmi et al., 2004). A pseudoinfection caused by *Tsukamurella paurometabola* was traced back to laboratory contamination (Auerbach et al., 1992).

Ecology. Tsukamurellae have been isolated from a range of aquatic and terrestrial habitats, as well as from clinical material. The type strains of *Tsukamurella paurometabola* and *Tsukamurella spongiae* were isolated from mycetomes and ovaries of the bed bug (*Cimex lectularius*) and from a deep-water marine hexactinellid sponge, respectively (Olson et al., 2007; Steinhaus, 1941). Representative strains isolated from activated sewage sludge foam have been classified into three novel species, namely *Tsukamurella pseudospumae* Nam et al. (2004), *Tsukamurella spumae* Nam et al. (2003a) and *Tsukamurella sunchonensis* Seong et al. (2003). The remaining species, *Tsukamurella inchonensis*, *Tsukamurella pulmonis*, *Tsukamurella strandjordii*, and *Tsukamurella tyrosinosolvens*, were isolated from clinical specimens (Kattar et al., 2001; Yassin et al., 1995, 1996, 1997). Several *Tsukamurella* strains have been isolated from Challenger Deep sediment (10,898 m) collected from the Mariana Trench in the Pacific Ocean (Pathom-aree et al., 2006).

Tsukamurella strains are considered to be one of the causal agents of foaming in activated sludge plants (Goodfellow et al., 1996; Seong et al., 1999). Large numbers of strains presumptively identified as tsukamurellae have been detected in mixed liquor ($2.7 \times 10^5 \pm 0.9$ c.f.u./ml) and foam ($9.3 \times 10^6 \pm 4.2$ c.f.u./ml) samples collected from Stoke Bardolph Water Reclamation Works, Nottinghamshire, UK (Stainsby, 2002). Pyrolysis mass spectrometric analysis of representative isolates confirmed their assignment to the genus *Tsukamurella* (Goodfellow et al., 1998) and showed that many of them belonged to a taxon, members of which were subsequently given species status as *Tsukamurella spumae* (Nam et al., 2003a). The type strain of *Tsukamurella paurometabola* has been shown to give a positive result against anti-*Gordonia amarae* mycolic acid polyclonal antibodies in an enzyme-linked immunosorbent assay (Iwahori et al., 2001).

Enrichment and isolation procedures

A semisolid medium containing carbohydrates, gelatin, proteose peptone, rabbit serum, and mineral rabbit kidney, was used in the original isolation of *Tsukamurella paurometabola* (Steinhaus, 1941). When transferred to brain heart infusion agar the organism grew in 24–28 h. *Tsukamurella strandjordii* and *Tsukamurella tyrosinosolvens* were obtained from blood cultures (Kattar et al., 2001; Yassin et al., 1997), and *Tsukamurella pulmonis* from

sputum following decontamination with *N*-acetyl-L-cysteine, centrifugation and cultivation on Lowenstein–Jensen's medium (Yassin et al., 1997). *Tsukamurella spongiae* was isolated from a sponge suspension which had been heat pretreated (70°C for 15 min), plated onto maltose-sea water agar (Olson et al., 2000), and incubated for 28 d in the dark at ambient temperature. Colonies were transferred to fresh plates of the isolation medium and finally maintained on slants of marine agar 2216 (Becton Dickinson). The *Tsukamurella* strains from the Challenger Deep sediment were isolated on Difco marine agar 2216 (Pathom-aree et al., 2006).

Large numbers of *Tsukamurella* strains have been isolated on glucose-yeast extract agar plates (Gordon and Mihm, 1962) supplemented with cycloheximide, and incubated at 30°C for 14 d following inoculation with serially diluted samples taken from foaming activated sludge plants (Goodfellow et al., 1998, 1996). The tsukamurellae were recognized by their ability to produce characteristic deep orange, dry colonies. Preliminary characterization studies indicated that representative isolates belonged to several new centers of taxonomic variation within the genus *Tsukamurella*. More exacting taxonomic studies showed that some of these isolates belong to *Tsukamurella pseudospumae* and *Tsukamurella spumae* (Nam et al., 2003a, 2004). Tsukamurellae have also been isolated from foaming activated sludge plants by micromanipulation (Seong et al., 1999).

Maintenance procedures

Short term storage can be accomplished by serial transfer every two months using appropriate media, such as modified Bennett's agar (Jones, 1949) and glucose-yeast extract agar (Gordon and Mihm, 1962) slopes with storage at 4°C. Longer term preservation of strains can be achieved as frozen stocks in 20% (v/v) aqueous glycerol at −20°C or −80°C (liquid nitrogen vapor phase) or by using standard lyophilization techniques as described for *Gordonia* strains.

Differentiation of the genus *Tsukamurella* from other genera

The type strains of *Tsukamurella* species form a distinct monophyletic lineage in the *Corynebacteriales* 16S rRNA tree (Figure 101). *Tsukamurella* strains can be distinguished from all other genera containing mycolic acids using a combination of chemotaxonomic and morphological markers (Table 29, in the *Corynebacteriales* chapter, above). There is also evidence that they can be distinguished by diagnostic 16S rRNA signatures at positions 1007:1022 (G-U), partial sequencing of ribosomal protein AT-L30 (Ochi, 1995), and by DNA amplification and restriction analysis (Steingrübe et al., 1997).

Taxonomic comments

The genus *Tsukamurella* Collins et al. 1988 is the type and only genus of the family *Tsukamurellaceae*. The taxon was introduced for actinomycetes previously classified as *Corynebacterium paurometabolum* and *Rhodococcus aurantiacus*. *Corynebacterium paurometabolum* was proposed by Steinhaus (1941) for bacteria isolated from the mycetomes and ovaries of the bed bug (*Cimex lectularis*) though its inclusion in the genus *Corynebacterium* was questioned (Collins and Cummins, 1986; Collins and Jones, 1982; Jones, 1975). Like corynebacteria, *Corynebacterium paurometabolum* has a directly cross-linked peptidoglycan based on *meso*-diaminopimelic acid and an arabinogalactan polymer (Cummins, 1971; Schleifer and Kandler, 1972), but can be distinguished from them as it contains a series of very long (68–76 carbon atoms), highly unsaturated (2–6 double bonds) mycolic acids (Collins and Jones, 1982).

Rhodococcus aurantiacus was known to have a similar series of very long, highly unsaturated mycolic acids (Goodfellow et al., 1978; Tomoysau and Yano, 1984). This species was first described by Tsukamura and Mizuno (1971) as "*Gordonia aurantiaca*"; the type strain of this taxon was later found to fall outside the aggregate *Rhodococcus* cluster circumscribed by Goodfellow and Alderson (1977). Goodfellow et al. (1978) found that "*Gordonia aurantiaca*" strains formed a well-delineated group that was distinct from the genera *Mycobacterium*, *Nocardia*, and *Rhodococcus* and thereby considered that the taxon merited generic status. However, around the same time, "*Gordonia aurantiaca*" was transferred to the genus *Rhodococcus* as *Rhodococcus aurantiacus* (Tsukamura, 1974, 1978; Tsukamura and Yano, 1985). In addition to their distinctive mycolic acid profile, *Corynebacterium paurometabolum* and *Rhodococcus aurantiacus* strains differed from other mycolic-acid-containing taxa as they produce menaquinones with unsaturated multiprenyl side chains (Collins and Jones, 1982).

Collins et al. (1988) concluded, mainly from 16S rRNA gene similarity data, that *Corynebacterium paurometabolum* and *Rhodococcus aurantiacus* were closely related but distinct from the genera *Corynebacterium*, *Mycobacterium*, *Nocardia*, and *Rhodococcus*. On the basis of this and previous findings, they proposed that *Corynebacterium paurometabolum* and *Rhodococcus aurantiacus* be reduced to a single species and classified in a new genus, *Tsukamurella*, as *Tsukamurella paurometabolum* comb. nov. This species epithet was subsequently corrected to *paurometabola* as the noun *Tsukamurella* is feminine, hence the corresponding adjective should have a feminine ending (Euzéby, 1998). The original type strains of *Corynebacterium paurometabola* and *Rhodococcus aurantiacus* strains were shown to belong to different species (Auerbach et al., 1992; McNabb et al., 1997); the type strain of *Rhodococcus aurantiacus* was eventually found to be a typical strain of *Tsukamurella inchonensis* based on DNA–DNA and phenotypic data (Nam et al., 2003a). In contrast, *Tsukamurella wratislaviensis* Goodfellow et al. (1991) was transferred to the genus *Rhodococcus* as *Rhodococcus wratislaviensis* comb. nov. following a polyphasic taxonomic study (Goodfellow et al., 2002).

The genus *Tsukamurella* contains nine validly named species which form a distinct clade in the *Corynebacteriales* 16S rRNA gene tree (Adachi et al., 2007; Goodfellow and Maldonado, 2006). The type strains of these species share very high 16S rRNA gene nucleotide similarity values, but can be distinguished by DNA–DNA relatedness and phenotypic data (Kattar et al., 2001; Nam et al., 2003a, 2004; Olson et al., 2007). The type strains of *Tsukamurella paurometabola* and *Tsukamurella spumae* show distinct ribotype patterns (Nam et al., 2003a). However, the taxonomic positions of some strains classified as *Tsukamurella paurometabola* need to be resolved as they are misplaced in this species (Nam et al., 2003a).

Differentiation of the species of the genus *Tsukamurella*

Tsukamurella species can be distinguished from one another by using a combination of phenotypic properties (Table 51). Preliminary studies suggest that *groEL* gene sequencing may give sufficient resolution to distinguish between *Tsukamurella* species (Woo et al., 2003).

List of species of the genus *Tsukamurella*

1. **Tsukamurella paurometabola** corrig. (Steinhaus 1941) Collins, Smida, Dorsch and Stackebrandt 1988, 387[VP] (*Corynebacterium paurometabolum* Steinhaus 1941, 783)

pau.ro.me.ta'bo.la. Gr. adj. *pauros* little; Gr. adj. *metabolos* changeable; N.L. fem. adj. *paurometabola* little changeable.

Strictly aerobic, Gram-stain-positive, straight to slightly curved rods (0.5–0.8 × 1.0–5 µm) found singly, in pairs, or in masses. Coccobacillary forms occur. Small, white, to creamish colonies (0.5–2.0 mm in diameter) with entire edges are formed. Colonies are dry, but easy to emulsify. Metachromatic granules may be detected. Grows at 10 and 45°C. Does not survive heating at 60°C for 15 min.

Positive for β-galacturonidase, pyrazinamidase, and urease, but negative for arylsulfatase and α-esterase. Does not reduce nitrate. Acetamide and nicotinamide are used as sole nitrogen sources, but benzamide is not. Resistant (µg/ml) to ethambutol (5), 5-fluorouracil (20), mitomycin C (10), and picric acid (0.2%, w/v), but susceptible to bleomycin (5).

Additional phenotypic properties are shown in Table 51.

Mycolic acids have 62–78 carbon atoms. The major cellular fatty acids are hexadecanoic (25.4%), oleic (23.5%), and tuberculostearic (17.9%) acids. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol

mannosides. The predominant menaquinone is MK-9; minor amounts of MK-7, MK-8, and MK-10 are also present.

Source: clinical material and the mycetomes and ovaries of bed bugs (*Cimex letularius*).

DNA G+C content (mol%): 67–68 (T_m).

Type strain: JC7,ATCC 8368, CCUG 35730, CIP 100753, CECT 3055, DSM 20162, NBRC 16120, JCM 10117, NCTC 13040.

Sequence accession no. (16S rRNA gene): AF283280, FJ468341, X53206, X80628, Z46751.

2. **Tsukamurella inchonensis** Yassin, Rainey, Brzezinka, Burghardt, Lee and Schaal 1995, 526[VP]

in.cho.nen′sis. N.L. fem. adj. *inchonensis* of or belonging to Inchon, the city in South Korea where the type strain was isolated.

Aerobic, Gram-stain-positive, acid–alcohol-fast bacilli. Visible growth from dilute inocula occurs within 2 d. Eugonic, rough, brownish-orange colonies are formed on Lowenstein–Jensen medium. Grows at 24 and 45°C, but not at 10°C. Acetamidase, allantoinase, thermostable catalase, β-glucosidase, β-galactosidase, nicotinamidase, pyrazinamidase, and urease positive, but negative for arylsufatase, benzamidase, nitrate reductase, and succinamidase. Acid is formed from cellobiose, fructose, galactose, glucose, inositol, maltose, mannitol, mannose, melezitose, sorbitol, sucrose, and trehalose, but not from adonitol, inulin, lactose, raffinose, rhamnose, or xylose. Resistant to *p*-aminosalicylic acid, capreomycin, cycloserine, ethambutol, isoniazid, protionamide, and rifampin. Grows on MacConkey agar without crystal violet, and tolerates 5% (w/v) sodium chloride and *p*-nitrobenzoic acid.

Additional phenotypic properties are shown in Table 51.

Contains α- and α′ mycolates. The major cellular fatty acids are hexadecanoic (31.3%), oleic (27.4%), and tuberculostearic (14.6%) acids. The predominant menaquinone is MK-9; minor amounts of MK-8 and MK-10 are also present.

Source: clinical material.

DNA G+C content (mol%): 72 (HPLC).

Type strain: IMMIB D-771, ATCC 700082, CIP 104790, DSM 44067, JCM 10110.

Sequence accession no. (16S rRNA gene): AF 283281, X85955.

Additional comment: Tsukamurella paurometabola ATCC 25938 is a misnamed *Tsukamurella inchonensis* strain.

3. **Tsukamurella pseudospumae** Nam, Kim, Chun and Goodfellow 2004, 1211[VP]

pseu.do.spu′ma.e. Gr. adj. *pseudês* false; L. gen. n. *spumae* of foam and specific epithet of a bacterial species; N.L. gen. n. *pseudospumae* the false *spumae*, referring to the close relationship to *Tsukamurella spumae*.

Aerobic, Gram-stain-positive, partially acid–alcohol-fast actinomycetes which form straight to slightly curved rods and a few long filaments. Large orange to red colonies (<5 mm) with irregular margins are formed on glucose-yeast extract agar. Grows at 10 and 37°C, but not at 45°C. L-Phenylalanine is used as a sole carbon and nitrogen source, but histidine, lysine, succinamide, and valine are not. Resistant (µg/ml) to bekanamycin (64), 5-fluorouracil (20), gentamicin (32), kanamycin (32), neomycin (32), novobiocin (16), oleandomycin (64), rifamycin (2), tetracycline (10), and vancomycin (4), but is susceptible to chlortetracycline (8), erythromycin (8), novobiocin (64), penicillin (64), and rifampin (16). Grows in the presence of crystal violet (0.001%, w/v).

Additional phenotypic properties are shown in Table 51.

Mycolic acids have 68–76 carbon atoms and up to 7 double bonds; the major products from pyrolysis gas chromatography of methyl mycolates are straight-chain fatty acids $C_{20:1}$ and $C_{22:1}$. The major cellular fatty acids are hexadecanoic (23.3%), oleic (29.9%), and tuberculostearic (15.2%) acids. The predominant menaquinone is MK-9.

Source: activated sludge foam.

DNA G+C content (mol%): not determined.

Type strain: N1176, DSM 44118, JCM 13375, NCIMB 13963.

Sequence accession no. (16S rRNA gene): AY238513.

4. **Tsukamurella pulmonis** Yassin, Rainey, Brzezinka, Burghardt, Rifai, Seifert, Feldmann and Schaal 1996, 434[VP]

pul.mo′nis. L. gen. masc. n. *pulmonis* of the lung, referring to the organ from which the bacterium was isolated.

Aerobic, Gram-stain-positive, and slightly acid–alcohol-fast bacilli. Most cells are long rods which, at a later stage of growth fragment into three parts which separate and grow as independent rods. Visible growth from dilute inocula occurs within 2 d. Eugonic, rough, creamy colored colonies are formed on brain heart infusion agar and Löwenstein–Jensen medium. Grows at 24 and 37°C, but not at 10 or 45°C. Does not form melanin pigments on either peptone-yeast extract-iron (ISP medium 6) or tyrosine (ISP medium 7) agars. Acid is produced from fructose, galactose, glucose, mannose, mannitol, sorbitol, sucrose, and trehalose, but not from adonitol, arabinose, cellobiose, inositol, inulin, lactose, maltose, melezitose, raffinose, rhamnose, or xylose. Resistant to *p*-aminosalicylic acid, capreomicin, cycloserine, ethambutol, isoniazid, protionamide, rifampin, and streptomycin. Grows on MacConkey agar without crystal violet and tolerates 5% (w/v) sodium chloride and *p*-nitrobenzoic acid.

Additional phenotypic properties are shown in Table 51.

Contains α- and α′-mycolic acids. The major cellular fatty acids are hexadecanoic (29.7%), oleic (33.5%), and tuberculostearic (9.3%) acids. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The predominant menaquinone is MK-9; minor amounts of MK-8 and MK-10 are also present.

Source: clinical material.

DNA G+C content (mol%): 69.8 (HPLC).

Type strain: IMMIB D-1321, ATCC 700081, CCUG 35732, CIP 104791, DSM 44142, JCM 10111.

Sequence accession no. (16S rRNA gene): X92981.

5. **Tsukamurella spongiae** Olson, Harmody, Bej and McCarthy 2007, 1480[VP]

spon′gi.a.e. L. gen. n. *spongiae* of a sponge, referring to the source of isolation, a deep-water sponge.

Aerobic, Gram-stain-positive organism which forms straight to slightly curved rods (1 × 2.5 µm). Grows on brain heart infusion, nutrient, and marine agars after 24–48 h incubation at ambient temperature (about 25°C). Colonies are dry,

matt, and cream colored with irregular spreading margins and raised, wrinkled, rough centers; they range in size from 2–5 mm in diameter and show irregular variation. Optimal temperature for growth is 25–37°C; does not grow at 10°C or above 45°C. Galactose, glucose, mannose, rhamnose, sucrose, and trehalose are used as sole carbon sources, but amyl alcohol and methanol are not. Tolerates NaCl concentrations up to 4% (w/v), but growth is enhanced at lower concentrations.

Additional phenotypic properties are shown in Table 51.

Mycolic acids have 58–75 carbon atoms. The major cellular fatty acids are $C_{18:1}$ ω9*c* (40.7%), $C_{16:0}$ (27.7%), and $C_{16:1}$ ω7*c* and/or C_{15} iso 2-OH (10.3%); small proportions of tuberculostearic acid (1.5%) are also present.

Source: a deep-water sponge collected off the coast of Curaçao in the Netherlands Antilles, at a depth of 220 m.

DNA G+C content (mol%): 74.6 (T_m).

Type strain: K362, DSM 44990, JCM 14882, NRRL B-24467.

Sequence accession no. (16S rRNA gene): AY714239.

6. **Tsukamurella spumae** Nam, Chun, Kim, Kim, Zakrzewska-Czerwinska and Goodfellow 2003b, 1701[VP] (Effective publication: Nam, Chun, Kim, Kim, Zakrzewska-Czerwinska and Goodfellow 2003a, 373.)

spu′ma.e. L. gen. n. *spumae* of foam denoting the presence of the organism in the foam of activated sewage sludge plants.

Aerobic, Gram-stain-positive, partially acid–alcohol-fast organism which forms straight to slightly curved rods and a few long filaments. Large orange to red colonies (<5 mm) with irregular margins and elevation are formed on glucose–yeast extract agar. Grows at 10 and 37°C, but not at 45°C. Phenylalanine is used as a sole carbon and nitrogen source, but histidine, lysine, succinamide, and valine are not. Resistant (µg/ml) to bekanamycin (64), erythromycin (8), 5-fluorouracil (20), gentamicin (32), kanamycin (64), neomycin (32), novobiocin (16), oleanodomycin (64), rifampin (2), and vancomycin (4), but susceptible to chlortetracycline (8), erythromycin (16), novobiocin (64), penicillin G (64), and rifampin (16). Grows in the presence of crystal violet (0.001%, w/v).

Additional phenotypic properties are shown in Table 51.

Mycolic acids have 68–76 carbon atoms and up to 7 double bonds; the major products from pyrolysis gas chromatography of methyl mycolates are straight chain fatty acids $C_{20:1}$ and $C_{22:1}$. The major cellular fatty acids are hexadecanoic (26.5%), oleic (26.9%), and tuberculostearic (17.5%) acids. The predominant isoprenologue is MK-9.

Source: activated sludge foam.

DNA G+C content (mol%): 70 (T_m).

Type strain: N1171, CCUG 48751, DSM 44113, JCM 12608, NCIMB 13947.

Sequence accession no. (16S rRNA gene): Z37150.

7. **Tsukamurella strandjordii** corrig. Kattar, Cookson, Carlson, Stiglich, Schwartz, Nguyen, Daza, Wallis, Yarfitz and Coyle 2002, 1075[VP] (Effective publication: Kattar, Cookson, Carlson, Stiglich, Schwartz, Nguyen, Daza, Wallis, Yarfitz and Coyle 2001, 1474.)

strand.jor′di.i. N.L. gen. masc. n. *strandjordii* of Strandjord, named in honor of Paul Strandjord, founder and chair of the Department of Laboratory Medicine, University of Washington, from 1969 to 1994.

Strictly aerobic, Gram-stain-positive, slightly acid-fast organism which forms long rods. Grows well after incubation for 2 d on MacConkey agar without crystal violet and on Middlebrook 7H11 and tryptic soy agars. Colonies (2–5 mm) are rough and tan to yellow in color. Short, branching substrate hyphae and diphtheroid forms are produced on tap water agar. Grows at 28 and 35°C, but not at 10 or 42°C. Semi-quantitative catalase, 68°C heat-stable catalase, and iron uptake tests are positive. Nitrate is not reduced. Positive for L-leucyl-2-naphthylamide, bromo-2-naphthyl-β-D-glucopyranoside, 2-naphthylcaprylate, 2-naphthyl-α-D-glucopyranoside, and 2-naphthylphosphate (API ZYM system), and for pyrazinamidase and urease, but is arylsulfatase negative (3 and 14 d). Utilizes D- and L-arabitol, arbutin, fructose, fucose, galactose, glucose, gluconate, inositol, maltose, mannitol, mannose, melezitose, α-methyl-D-glucoside, sucrose, salicin, sorbitol, trehalose, and turanose (API 50 CH system). Susceptible to amikacin, clarithromycin, ciprofloxacin, imipenem, and trimethoprim sulfamethoxazole.

Additional phenotypic properties are shown in Table 51.

HPLC analyses of mycolic acids yield similar chromatographic profiles to those of other *Tsukamurella* species. The major cellular fatty acids are hexadecanoic (40.3%), oleic (23.7%), and tuberculostearic (16.5%) acids.

Source: blood of a 5-year-old girl with acute mycelogenous leukemia.

DNA G+C content (mol%): not determined.

Type strain: 32-92, ATCC BAA-173, DSM 44573, JCM 11487.

Sequence accession no. (16S rRNA gene): AF 283283.

8. **Tsukamurella sunchonensis** Seong, Kim, Baik, Choi, Kim, Kim and Goodfellow 2008, 1993[VP] (Effective publication: Seong, Kim, Baik, Choi, Kim, Kim and Goodfellow 2003, 88.)

sun.chon.en′sis. N.L. fem. adj. *sunchonensis* of or belonging to Sunchon, a city in South Korea where the organism was isolated.

Aerobic, Gram-stain-positive, slightly acid–alcohol-fast bacilli. Rough, orange colored colonies formed on yeast extract-malt extract agar. Dilute inocula on brain heart infusion agar yield large eugenic cream-colored colonies. Does not form melanin pigments. Grows at 28 and 37°C, but not at 10 or 45°C. Nitrate is not reduced. Does not degrade adenine, casein, elastin, gelatin, pectin, gelatin, starch, Tween 80, or xanthine. Acid is produced from fructose, glucose, maltose, melezitose, sucrose, trehalose, and xylose, but not from adonitol, maltose, mannose, or raffinose. Galactose, glucose, *meso*-inositol, and trehalose are used as sole carbon sources, but adonitol, dextran, lactose, melibiose, raffinose, and rhamnose are not. Sensitive (µg/ml) to gentamicin (10), rifampin (50), streptomycin (10), tobramycin (10), and vancomycin (30), but resistant to bacitracin (10 IU) and penicillin G (10 IU). Grows in the presence of phenol (0.1%, w/v), potassium tellurite (0.01%, w/v), and sodium chloride (7%, w/v), but is sensitive to crystal violet (0.0001, w/v), sodium azide (0.02%, w/v), and sodium chloride (10%, w/v).

Contains α- and α′-mycolates. The major cellular fatty acids are hexadecanoic (37.8%), oleic (32.6%), and tuberculostearic (11.5%) acids. The predominant menaquinone is MK-9.

Source: activated sludge foam.

DNA G+C content (mol%): 68.1 (slot dot method).

Type strain: SCNU5, JCM 15929, KCTC 9827, NRRL B-24668.

Sequence accession no. (16S rRNA gene): AF150494.

9. **Tsukamurella tyrosinosolvens** Yassin, Rainey, Burghardt, Brzezinka, Schmitt, Seifert, Zimmermann, Mauch, Gierth, Lux and Schaal 1997, 612[VP]

ty.ro.si.no.sol′vens. N.L. n. *tyrosinum* (from Gr. masc. n. *tyros* cheese) tyrosine an amino acid; L. pres. part. *solvens* dissolving; N.L. part. adj. *tyrosinosolvens* tyrosine dissolving, referring to the hydrolysis of tyrosine which is characteristic of this species.

Aerobic, Gram-stain-positive, and slightly acid–alcohol-fast bacilli. Most cells are long rods which, at a late stage of growth, fragment into three parts which separate and grow into independent rods. Visible growth from dilute inocula occurs within 2 d; colonies on brain heart infusion agar are yellowish, dry, and rough. Melanin pigments are not formed on either peptone-yeast extract-iron (ISP medium 6) or tyrosine (ISP medium 7) agars. Grows at 24 and 37°C, but not at 10 or 45°C. Acetamidase, allantoinase, catalase, β-galactosidase, nicotinamidase, phosphatase, pyrazinamidase, and urease positive, but negative for arylsulfatase (after 3 d), benzamidase, nitrate reductase, and succinamidase. Acid is produced from fructose, galactose, glucose, *meso*-inositol, maltose, mannitol, mannose, melezitose, sorbitol, sucrose, and trehalose, but not from adonitol, L-arabinose, cellobiose, inulin, lactose, raffinose, rhamnose, or xylose. Resistant to capreomycin, cycloserine, ethambutol, isoniazid, *p*-aminosalicylic acid, protionamide, rifampin, and streptomycin.

Additional phenotypic properties are shown in Table 51.

Contains α- and α′-mycolic acids. The major cellular fatty acids are hexadecanoic (34.2%), oleic (34.4%), and tuberculostearic (8.1%) acids. The cellular polar lipid composition is diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol and phosphatidylinositol mannosides. The predominant menaquinone is MK-9; minor amounts of MK-8 and MK-10 are also present.

Source: blood cultures.

DNA G+C content (mol%): 69–74 (HPLC).

Type strain: IMMIB D-1397, CCUG 38499, DSM 44234, JCM 10112.

Sequence accession no. (16S rRNA gene): AY 238514.

Order VI. **Frankiales** ord. nov.

PHILIPPE NORMAND AND DAVID R. BENSON

Fran.ki′a.les. N.L. fem. n. *Frankia* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Frankiales* the *Frankia* order.

The order *Frankiales* is formed by elevation of the suborder *Frankineae* (Stackebrandt et al., 1997). It is currently composed of bacteria that were treated differently in the last edition of the *Bergey's Manual of Systematic Bacteriology* (Williams, 1989). In that edition, section 27 was termed "Actinomycetes with multilocular sporangia" and contained the three genera *Frankia*, *Geodermatophilus*, and *Dermatophilus* (Lechevalier, 1989), members of which all produced spores in multilocular sporangia by septation in several planes. However, the taxa covered in this section turned out to be polyphyletic (Hahn et al., 1989). In addition to genera with a large number of species, like *Streptomyces* and *Streptoverticillium*, section 29 contained the formerly monospecific genus *Sporichthya*, which produces chains of spores, and the genus *Kineosporia* that had no features in common with the other genera except substrate hyphae (Locci, 1989). The current treatment clusters taxa on the basis of similarities in their 16S rRNA gene sequences, with the result that some additional genera are now included in the order *Frankiales*. Many of the taxa included in the *Frankiales* have little in common with the exception of similar 16S rRNA gene sequences (Table 52). This unusual situation is presumably the result of an adaptable ancestral bacterium that evolved to occupy markedly different ecological niches. These niches include root nodules of woody dicots, hot springs, rocky surfaces, gamma-irradiated substrates, activated sludge, compost, and, of course, soil. This range of ecological specialization is probably the most diverse in a single microbial order with only pathogens missing from the group now that *Dermatophilus* has been reassigned to family *Dermatophilaceae*, order *Micrococcales*, following the 16S rRNA gene sequencing analysis of Hahn et al. (1989). Understanding how the ancestor differentiated into the six known families is the subject of many genomics projects currently under way.

The current order is based on a number of 16S rRNA gene sequence analyses. While the original analyses suggested that *Kineosporia* was affiliated to this group in a novel family "*Kineosporiaceae*" (Lilburn and Garrity, 2004), subsequent analyses indicated that this genus represented a novel order, *Kineosporiales* (Zhi et al., 2009; Ludwig et al., this volume). In addition, the genus *Cryptosporangium* was transferred from the family "*Kineosporiaceae*" to a new family *Cryptosporangiaceae*, which remained with the order *Frankiales*. Even with these reclassifications, the order may be an artificial category in the sense that the groupings vary depending on the tree-reconstruction algorithm used. The family *Nakamurellaceae* (formerly *Microsphaeraceae*) is positioned here only artefactually, whereas the others constitute a more solid entity more likely to survive the rearrangements expected as a result of the whole-genome analyses, which are underway.

The order contains the family *Frankiaceae*, which contains symbiotic bacteria, as well as families containing non-symbiotic bacteria: *Geodermatophilaceae*, *Nakamurellaceae*, *Sporichthyaceae*, *Acidothermaceae*, and *Cryptosporangiaceae*. Phylogenetic analysis (neighbor-joining tree) based on 16S rRNA gene sequences shows the relationships between the six families, with *Nakamurellaceae* as the basal group, a large subgroup containing the *Frankiaceae*, the *Acidothermaceae*, the *Geodermatophilaceae*, the *Cryptosporangiaceae*, and the *Sporichthyaceae* (Figure 102).

Type genus: **Frankia** Brunchorst 1886, 174[AL].

TABLE 52. Distinguishing features of the six families of the order *Frankiales*[a]

Characteristic	*Frankiaceae*	*Acidothermaceae*	*Cryptosporangiaceae*	*Geodermatophilaceae*	*Nakamurellaceae*	*Sporichthyaceae*
Morphology:						
Hyphae	++	+/−	++	+/−	−	+/−
Rods	−	+/−	+/-	−	+	+/−
Sporangia	++	−	+/-	++	−	+/−
Vesicles	+	−	−	−	−	−
Physiology:						
Motility	−	−[b]	+/-	+	−	+
Temperature range (°C)	10–35[c]	37–70	10-37	10–37	10–35	10–42
Oxygen requirement	Microaerophilic	Aerobic	Aerobic	Aerobic	Aerobic	Aerobic
Growth rate	Slow (>15 d)	Fast (2 d)	Slow (>14 d)	Fast (2 d)	Slow (10 d)	Fast (24 h)
N_2 fixation	+	−	nd	−	−	−
Chemistry:						
Diamino acid	*meso*-DAP	−	*meso*-DAP	*meso*-DAP	*meso*-DAP	L-DAP
Menaquinone	$9(H_4)$, $9(H_6)$, $9(H_8)$	nd	$9(H_6)$, $9(H_4)$, $9(H_8)$	$9(H_4)$, $8(H_4)$	$8(H_4)$	$9(H_6)$, $9(H_8)$, $8(H_6)$
Cellular fatty acids	$C_{15:0}$, $C_{16:0\ iso}$,$C_{17:1}$	nd	$C_{16:0}$ iso, $C_{18:1}$, $C_{17:1}$, 10-Me$C_{17:0}$, 10-Me$C_{18:0}$	$C_{16:0}$ iso, $C_{16:1}$, $C_{18:1}$	$C_{15:0}$ iso, $C_{16:0}$ iso, $C_{18:1}$ iso	$C_{16:0}$ iso, $C_{18:0}$, $C_{17:1}$
DNA G+C content (mol%)	66–74	66.9	65–76	68–75	67.5	71
Source	Soil/plant root	Thermal springs	Soil, rock surfaces	Soil, rock surfaces, sea	Sludge	Soil

[a]Symbols: ++, strongly positive; +, positive; +/−, positive or negative; −, negative; nd, no data.

[b]Genes for flagellar apparatus are present in the *Acidothermus cellulolyticus* genome, but no motile phase has been observed (Barabote et al., 2009).

[c]Temperature range for most strains is 25–32°C.

[d]Time necessary for appearance of colony on solid medium.

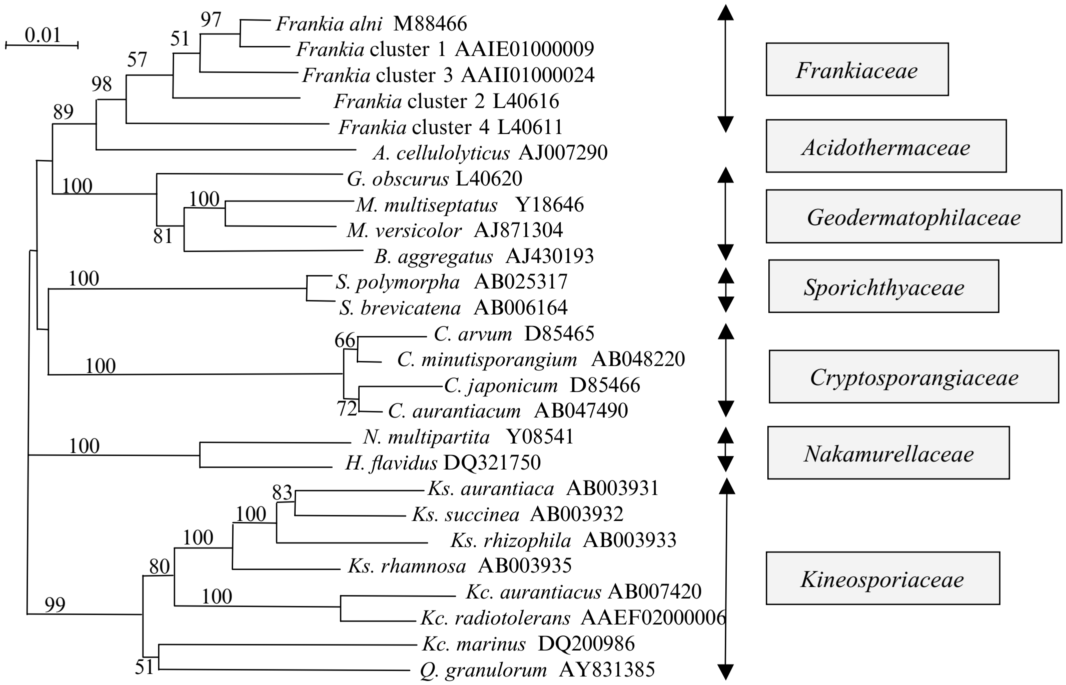

FIGURE 102. Phylogenetic tree of the families within the order *Frankiales*. Neighbor-joining tree (Saitou and Nei, 1987) of 16S rRNA gene sequences of all clusters (*Frankia*) and recognized species of the order *Frankiales*. Sequences were aligned using CLUSTAL X (Thompson et al., 1997), the distance matrix was calculated using Kimura's two-parameter method (1980), the robustness was estimated using the bootstrap method (Felsenstein, 1985), and the resulting topology is represented using NJPlot (Perrière and Gouy, 1996). Bootstrap values are shown at nodes. Bar = 0.01 substitutions per site. The tree is unrooted. The genus *Cryptosporangium* is representative of the family *Cryptosporangiaceae*. The family *Kineosporiaceae* is now classified in the order *Kineosporiales*. This topology is obtained with all tree reconstruction algorithms for these sequences (unpublished).

Fran.ki.a.ce′a.e. N.L. fem. n. *Frankia* type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Frankiaceae* the *Frankia* family.

Circumscription, position and rank

The *Frankiaceae* as emended by Hahn et al. (1989) included, besides the genus *Frankia* containing plant symbionts, the genus *Geodermatophilus* with members occupying soil and rock surfaces, and the skin pathogen *Dermatophilus*. These genera have sporangia formed by cells dividing in three planes. This feature was judged insufficient to warrant placing them in the same family by Normand et al. (1996), particularly considering their many ecological and biochemical differences and the fact that members of the genus *Acidothermus*, although closer phylogenetically to *Frankia*, did not form the multilocular sporangia deemed to be the hallmark of the taxon. The *Frankiaceae* is thus currently a family with only one genus. This situation may change since it is now known that several related slow-growing soil-inhabiting actinomycetes exist (Normand and Chapelon, 1997).

The family *Frankiaceae* was first proposed by Becking (1970) to group microbes, unisolated at the time, that inhabit the root nodules of woody dicots. Becking relied heavily on morphological features of the bacteria as they occurred in plant tissues and on cross-inoculation studies using crushed root nodules as the inoculum. The first isolation was accomplished 8 years after Becking's publication (Callaham et al., 1978), paving the way for isolation of many additional strains. With strains in hand, it became clear that Becking's proposal was untenable. Cross-inoculation with pure cultures showed that isolated strains had broader host ranges than indicated by endophyte suspensions and that the *in planta* morphology was under control of the host plant (Lalonde, 1979). A signature sequence 5′-TGCAAGTCGAGCGAGGGGCTT-3′ has been proposed as being genus-specific (Normand and Chapelon, 1997), even though phylogenetically related uncharacterized soil actinomycetes have been obtained by PCR. Given that there is only one genus in the family, this signature may be appropriate for the family as a whole. A 16S rRNA gene sequence signature nucleotide pattern consisting of 139:224 (G–C), 148:174 (A–G), 155:166 (U–G), 839:847 (A–G), 987:1218 (G–C), 1059:1198 (C–G), and 1308:1329 (C–G) has been proposed (Stackebrandt et al., 1997).

Type genus: **Frankia** Brunchorst 1886, 174^{AL}.

Genus I. **Frankia** Brunchorst 1886, 174^{AL}

Philippe Normand and David R. Benson

Fran′ki.a. N.L. fem. n. *Frankia* named after Albert Bernhard Frank (1839–1900), a Swiss plant biologist, who studied extensively nitrogen nutrition in legumes and the micro-organisms causing root nodulation from 1877 to 1892 and who coined the term "symbiosis".

Vegetative hyphae with limited to extensive branching, 0.5–2.0 µm in diameter and occasionally wider in older cultures. **No aerial mycelium is formed** on solid media. Intra- and extracellular pigments may be formed. **Gram-stain-positive** in healthy cultures; Gram-stain-variable in older cultures. **Aerobic to microaerophilic** with a respiratory type of metabolism. No growth factors are required. Does not grow under anaerobic conditions. Catalase-positive. Mesophilic. Chemoorganotrophic. Usually very **slow-growing** with doubling times of 20 h to several days. Most strains are capable of fixing N_2 both *in vitro* and *in planta*. Nonpathogenic to humans and animals (Gordon et al., 1983).

Round to irregularly shaped **multilocular sporangia** are borne terminally, laterally, or in an intercalary position on the vegetative hyphae. Lateral sporangia are usually borne on sporangiophores; some are sessile. Sporangia are up to 100 µm in length formed by septation in three planes of the cytoplasm of pre-existing thin-walled swellings. Sporangiospores are nonmotile, irregular (often somewhat polygonal) in shape, 1–5 µm in size, usually colorless, sometimes black, showing multilaminar outer membrane-like layers in thin section. Spores are not thermally resistant. Sporangiospores usually do not develop and mature simultaneously resulting in the presence of spores of different maturity levels in the same sporangium.

Unique terminal or laterally formed "vesicles" or "diazovesicles" may be formed. These structures are terminal hyphal swellings that become increasingly septate with age (Figure 103). They possess envelopes with up to 90 laminated layers composed chiefly of bacteriohopane and its derivatives (Berry et al., 1993; Harriott et al., 1991). They are the site of nitrogen fixation in cells deprived of combined nitrogen in culture and, in symbioses, where vesicles are formed (Benson and Silvester, 1993). Vesicles

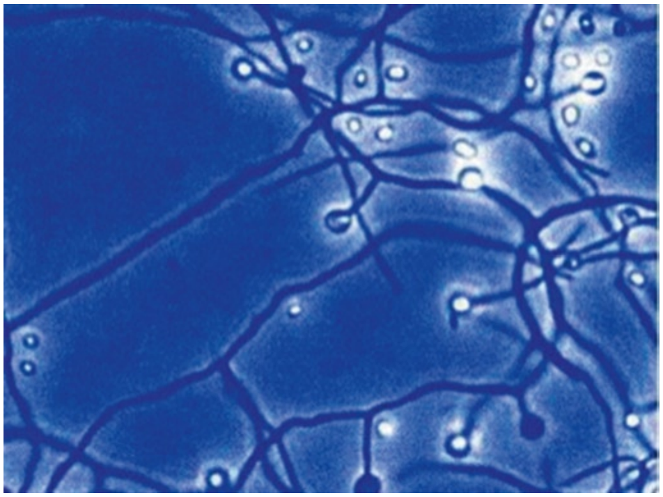

FIGURE 103. Culture of *Frankia alni* strain ACN14a showing vegetative branched septate hyphae as well as "diazovesicles", the thick-walled cells specializing in nitrogen-fixation (photo by Y. Hammad, Université Lyon 1-CNRS, France).

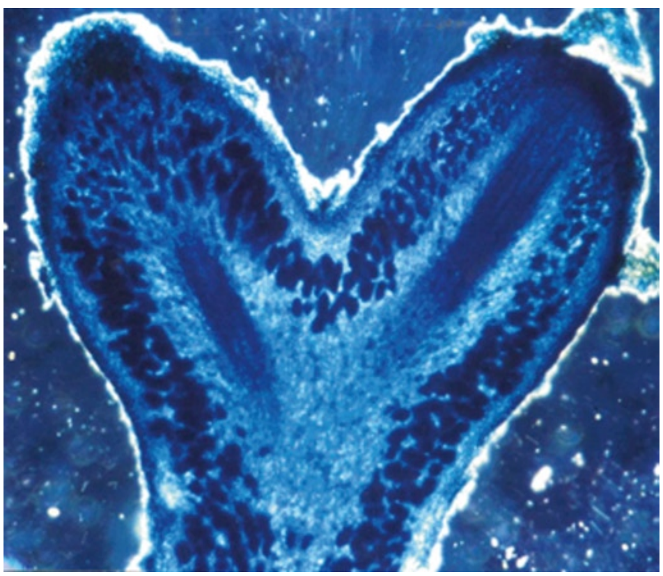

FIGURE 104. Longitudinal section of a dichotomous alder nodule stained to highlight the enlarged cortical cells packed with *Frankia* "diazovesicles". The basal diameter is about 2 mm (photo by P. Normand, Université Lyon 1-CNRS, France).

occasionally form under conditions where nitrogen fixation does not occur.

Cell walls contain *meso*-diaminopimelic acid (*meso*-DAP), glutamic acid, alanine, muramic acid, and glucosamine. No mycolates are present. Phospholipids comprise phosphatidylinositol mannosides, phosphatidylinositol, and diphosphatidylglycerol. Fatty acids are normal, branched-chain, and monounsaturated. Whole-cell sugar patterns show xylose (without arabinose), madurose, or fucose or cells may contain only glucose or galactose, sugars not previously found to have taxonomic significance in the *Actinomycetales.* **All strains tested contain 2-*O*-methyl-D-mannose** and most contain rhamnose. **Most strains are symbiotic with certain angiospermous plants**, inducing nodules on the roots of suitable hosts (Figure 104). May be found free in soil.

DNA G+C content (mol%): 66–73 (T_m).

Type species: **Frankia alni** (Woronin 1866) Von Tubeuf 1895, 118 (*Schinzia alni* Woronin 1866, 6).

Additional remarks: contains one recognized species, *Frankia alni*, and at least 12 genomospecies identified by DNA–DNA hybridization (Akimov and Dobritsa, 1992; An et al., 1985; Fernandez et al., 1989; Lumini et al., 1996). The other species described by Becking (1970) based on morphological descriptions of unisolated strains and on cross-inoculation data were later deemed to be invalid because it was found with the first isolates that the host plant determined the microbial *in planta* morphology (Lalonde, 1979).

Further descriptive information

Symbiotic relationships. Virtually all *Frankia* strains available in culture have been isolated or described in the context of the plant hosts from which they were isolated. Many additional strains have been identified by gene sequences obtained from field-grown root nodules during studies on strain diversity or population structure (Benson et al., 2004, 1996; Clawson et al., 1997, 1998, 1999, 2004; Clawson and Benson, 1999; Huguet et al., 2001, 2004, 2005a, 2005b; Jeong and Myrold, 1999; Oakley et al., 2004; Ritchie and Myrold, 1999a, 1999b; Simonet et al., 1999; Vanden Heuvel et al., 2004).

There are 23 genera of dicotyledonous plants, belonging to eight families, that have established symbiotic N_2-fixing root nodules with *Frankia* (Table 53; Benson and Silvester, 1993). The symbiosis is called "actinorhizal" and infected plants are referred to as "actinorhizal plants" (Torrey, 1983). Suitable plant hosts (Table 53) are readily infected by most frankiae, giving rise to nitrogen-fixing (effective) nodules on the roots. Some strains give rise to noneffective nodules and still others are not infective for the host plant from which they were isolated. The latter strains are often infective on plants belonging to the family Elaeagnaceae (Clawson et al., 2004; Gauthier et al., 1981). Infection in the Elaeagnaceae and in *Ceanothus* takes place by intercellular penetration into the root (Liu and Berry, 1991; Miller and Baker, 1985), whereas infection in other plants proceeds through root hairs (Berry and Sunell, 1990; Berry and Torrey, 1983; Callaham et al., 1979; Liu and Berry, 1991; Sunell and Berry, 1990). In cases where an "elaeagnus strain" infects plants from other families, the infection route is dictated by the plant as to whether it is via intercellular

[e] The infective strain group refers to the group of *Frankia* strains typically found in root nodules of each plant genus. A, alder strains; C, casuarina strains, E, elaeagnus strains, R, rosaceous strains. (E), Rare detection of an elaeagnus strain in a nodule or surface layers of a nodule (Benson et al., 2004).

penetration or the root hair (Miller and Baker, 1986; Racette and Torrey, 1989).

The molecular mechanisms whereby the plant recognizes the microbial symbiont and forms nodules are not currently known, except for the recently demonstrated role of SymRK kinase that is necessary for both nodule and mycorhiza formation (Gherbi et al., 2008). In *Frankia* genomes, canonical genes have not been identified (Normand et al., 2007a) and the factor that deforms *Alnus* root hairs has only been characterized as hydrophilic, thermostable, and sensitive to some enzymes such as pronase (Ceremonie et al., 1999).

Pure culture isolates have been obtained from most actinorhizal plant genera and families apart from the Rosaceae, the Coriariaceae, the Datiscaceae, and *Ceanothus* sp. in the Rhamnaceae (Table 53). Three clusters of symbiotic *Frankia* sp. strains are recognized in phylogenetic analyses of 16S rRNA genes and glutamine synthetases I and II (*glnA* and *glnII*) (Clawson et al., 2004; Cournoyer et al., 1993; Normand et al., 1996). Each cluster is characterized by the range of plants infected. Phylogenetic cluster 1 contains the species *Frankia alni*, as well as other strains infective and effective on *Alnus*, *Myrica*, and *Casuarina*. Phylogenetic cluster 2 is basal and includes strains that have been detected in nodules on the Rosaceae, Coriariaceae, Datiscaceae, and the Rhamnaceae of North America (*Ceanothus*), and have so far defied all isolation attempts. Phylogenetic cluster 3 contains strains infective on the Elaeagnaceae, *Gymnostoma* (Casuarinaceae), and the Rhamnaceae of South America. Strains from this group have also been isolated from nodules from other members of the Casuarinaceae; some of the latter strains are infective, but not effective (non-N_2-fixing) on *Alnus*. A fourth phylogenetic cluster, which contains noninfective strains as well as some strains that are infective but not effective on *Alnus*, appears to be basal to the clade.

Morphology. Some frankiae have loosely filamentous thalli with relatively little branching and hyphae that are about 1.0 µm in diameter. Others have finer hyphae (~0.5 µm), are more highly branched, and form compact, dense thalli. The hyphal filaments do not fragment, although in some isolates from *Casuarina*, the hyphae form elongated, narrow, sporangia-like structures with cross walls that break down into subunits under

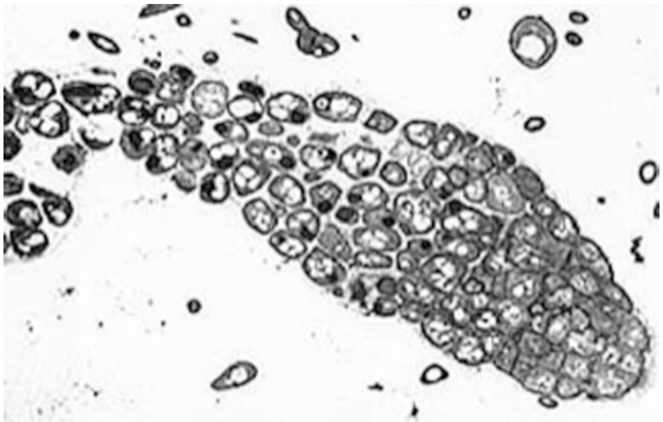

FIGURE 105. *Frankia* CeI5 sporangium (TEM) containing about 50 spores. The size is about 10 × 30 μm (photo by R.H. Berg, Integrated Microscopy Facility, Danforth Plant Science Center, St Louis, MO, USA).

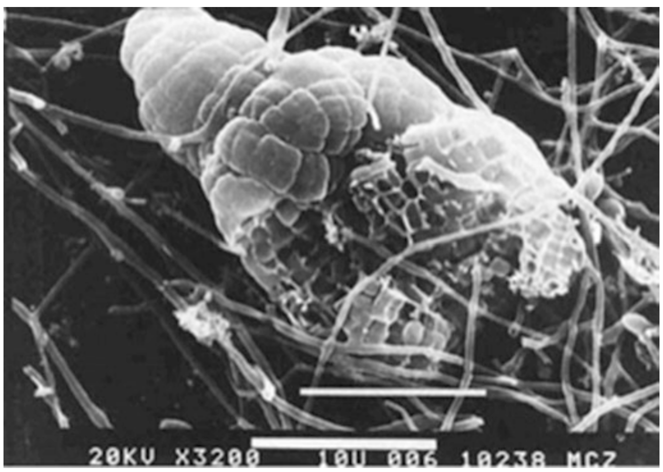

FIGURE 106. Multilocular sporangium and branched hyphae of *Frankia* sp. strain DDB 01020110 isolated from *Alnus viridis* subsp. *crispa* (photo by D.D. Baker and H.A. Lechevalier). Bar = 10 μm. [From the Digital Atlas of Actinomycetes (www.nih.go.jp/saj/DigitalAtlas/); copyright owned by The Society for Actinomycetes, Japan.]

pressure (Diem and Dommergues, 1985). Generally, the sporangia of the loosely filamentous type of strain are larger than in those that form compact colonies, and their mature spores are also larger (1.5–5 μm). Sporangial shapes are diverse, varying even within the same strain from round to highly irregular to elongate; most are multilocular (Figure 105). All spores examined to date are smooth-surfaced. Mature sporangiospores have thick walls and outer membrane-like layers that are similar to those associated with bacteriohopane layers on vesicles (Figure 106). Spores germinate at variable rates (usually very low) to give rise to 1–3 germ tubes for most strains. Sporangia are sometimes produced *in planta*, a characteristic that seems to be controlled genetically by the microorganism (Houwers and Akkermans, 1981; Normand and Lalonde, 1982; Van Dijk, 1978; VandenBosch and Torrey, 1984).

All *Frankia* strains tested make "vesicles" in N-deficient culture and often in symbiosis. Vesicles are lipid-encapsulated, roughly spherical cellular structures that measure between 2 and 6 μm in diameter. They are attached to hyphae by a short vesicle stalk that is also encapsulated. Vesicles contain the nitrogenase system and supporting enzymes. The lipid envelope consists of laminated layers of mainly bacteriohopanes that range from 10 to over 90 in number according to vesicle age and the pO_2 of the surrounding medium (Berry et al., 1993; Harriott et al., 1991; Lamont et al., 1988; Parsons et al., 1987; Torrey and Callaham, 1982). The layers are extracted during fixation for transmission electron microscopy, leaving a "void area" (Lalonde et al., 1976), but they can be visualized by permanganate fixation (Berg et al., 1999; Harriott et al., 1991). Each layer is about 4 nm thick. Bacteriohopanes play a role in membrane stability and fluidity (Poralla et al., 1980). In *Frankia* vesicles, they may limit oxygen diffusion into the O_2-labile nitrogenase (Berry et al., 1993). As vesicles senesce, septa become irregular, nitrogenase activity ceases, and the cytoplasm disappears. Some vesicles can, however, "germinate" and produce hyphae in culture (Schultz and Benson, 1989).

Physiology. In comparison with other actinobacteria, *Frankia* strains use a narrow range of carbon sources. Cluster 1 strains in particular seem limited to using organic acids such as short-chain fatty acids, tricarboxylic acid (TCA) cycle intermediates, or pyruvate as carbon sources. Sugars are not generally used, or are used slowly by strains in this group. Cluster 3 strains use a range of sugars or sugar alcohols including mannitol, fructose, and sorbitol. Growth on cellulose has been reported for one strain (Safo-Sampah and Torrey, 1988), but has not been confirmed by independent experiments. The genes for cellulase and pectinase are missing from the genomes of cluster 1 strains HFPCcI3 and ACN14a, but candidate genes for these enzymes are present in the cluster 3 strain EAN1pec (Normand et al., 2007b).

The most effective nitrogen source for growing *Frankia* is ammonia. It is assimilated primarily via the glutamine synthetase-glutamate synthase pathway (Tsai and Benson, 1989). Growth on individual amino acids is less effective unless a source of ammonia is provided either internally via N_2 fixation or externally in the medium. Cultures deprived of combined nitrogen, or cultivated in the presence of amino acids catabolized as glutamate rather than ammonia, develop vesicles and induce nitrogenase (Zhang and Benson, 1992). Thereupon, growth commences, but is slow relative to growth on ammonia.

As mentioned above, *Frankia* strains that currently have been cultured belong to clusters 1 and 3 of the major phylogenetic groups. No isolates from cluster 2 are available so far, despite numerous attempts on varied growth media. Cluster 1 strains appear similar to one another in culture with largely nonpigmented cells, except in older cultures, which tend to become yellow to red with extracellular pigments. These strains correspond to the group "B" *Frankia* described in a

previous treatment (Lechevalier and Lechevalier, 1989). Some tend to be microaerobic, growing into solid medium when plated and being relatively intolerant to aeration by shaking. As a group, they do not use carbohydrates up to 0.5% in the medium and instead prefer organic acids such as short-chain fatty acids (acetate, propionate), longer chain fatty acids supplied as Tweens or TCA cycle intermediates (succinate, malate), or pyruvate. Most of these strains induce effective (nitrogen-fixing) root nodules on their cognate hosts (Table 53). All strains tested to date also fix nitrogen in culture at atmospheric levels of oxygen or above and, when doing so, compartmentalize nitrogenase, nitrogenase reductase, and associated proteins in vesicles.

At present, two genomes are available from *Frankia* strains belonging to phylogenetic cluster 1. Analysis has confirmed the absence of the Entner–Doudoroff pathway and the presence of a complete Embden–Meyerhof–Parnas pathway, a pentose phosphate pathway, a TCA cycle, and all the components of oxidative phosphorylation. Strain HFPCcI3, a cluster 1 strain isolated from *Casuarina cunninghamiana* nodules, and EAN1pec, a cluster 3 strain isolated from *Elaeagnus angustifolia* root nodules, lack genes for isocitrate lyase in the glyoxylate pathway, but strain ACN14a, a cluster 1 strain, has the pathway genes, thus confirming its ability to grow on acetate or fatty acids. Since virtually all *Frankia* strains described to date have no growth factor requirements, biosynthetic pathways for vitamins, amino acids, nucleotides, and other essential metabolites are present in the genomes, including those for nitrogen fixation. The latter are clustered, in all cases, near the origin of replication.

Cluster 3 strains are typically pigmented, usually red in color, and tend to be more versatile physiologically than cluster 1 strains. They correspond to the group "A" *Frankia* strains of Lechevalier and Lechevalier (1989). On most media, they tend to grow faster than cluster 1 strains and can use carbohydrates such as fructose, mannitol, and sorbitol as sole carbon and energy sources. Strain EAN1pec possesses the components of the phosphotransferase system specific for fructose, sorbitol, and mannitol. In addition to sugars, most cluster 3 strains can also grow on short-chain fatty acids, especially propionate. One genome is available from a cluster 3 strain (EAN1pec). It can be distinguished from the cluster 1 genomes in being markedly larger with many gene duplicates and ancillary genes involving lipid and secondary metabolite metabolism not found in cluster 1 strains. Frankiae are sensitive to penicillin and streptomycin, but are naturally resistant to nalidixic acid.

Pigmentation and secondary metabolites. The capacity of *Frankia* strains to produce secondary metabolites has been highlighted by the recent availability of three genomes from cluster 1 (strains ACN14a and HFPCcI3) and cluster 3 (strain EAN1pec). Each genome contains several genes for polyketide synthases and non-ribosomal peptide synthetases; EAN1pec has the greatest number of such genes of any organism listed in the IMG database (version 1.3, December 2005; http://img.jgi.doe.gov/cgi-bin/pub/main.cgi). Each genome is also enriched with genes for lipid metabolism, similar to other actinobacteria. Secondary metabolites identified in *Frankia* have included red pigments identified as benzo[*a*]naphthacene quinones (Gerber and Lechevalier, 1984; Rickards, 1989) and calcimycins [demethyl (C-11) cezomycin] (Haansuu et al., 2001; Klika et al., 2001) that have some antibiotic activity. The number of biosynthetic genes identified in extant genomes suggests that many other secondary metabolites remain to be characterized from these organisms. *Frankia alni* has also been shown to produce phenylacetate in pure culture (Hammad et al., 2003), a compound known to have antifungal and antibacterial activity (Hwang et al., 2001).

Enrichment and isolation procedures

Pommer (1959) reported the first successful isolation of a *Frankia* strain from *Alnus glutinosa* root nodules using glucose-asparagine agar. The strain was subsequently lost, but drawings made by Pommer show typical *Frankia* morphology including sporangia and vesicles. Subsequently, Callaham et al. (1978) obtained a confirmed isolate (HFPCpI1) using microdissected vesicle clusters from nodules of *Comptonia peregrina* plated on a yeast extract-water agar medium. Once the slow-growing nature of the organism and its overall morphology were recognized, dozens of isolates from various laboratories became available over the next few years. Most available strains have no special growth requirements beyond a simple carbon source, ammonia, and mineral salts. Techniques for isolation have generally included pre-treating root nodules to separate or eliminate contaminants that otherwise quickly outgrow frankiae. The pre-treatments include soaking nodule pieces in surface-sterilizing agents such as mercuric chloride (Callaham et al., 1978), chloramine T (Diem et al., 1982), sodium hypochlorite (Baker and Torrey, 1979), and hydrogen peroxide (Zhongze et al., 1984). Isolation procedures have involved serial dilution of crushed nodule suspensions, microdissection of the nodule with or without pre-treatment with such cellulase or pectinase, and separation by sucrose gradient centrifugation followed by direct plating. The simplest and most effective method is that described by Benson (1982) involving the separation of vesicle clusters from plant material and contaminants by filtration through nylon screens followed by pour plating.

A variety of media has been used for isolation attempts including glucose-asparagine agar used initially by Pommer 1959, 0.5% yeast extract (Callaham et al., 1978), QMod (peptone, yeast extract, phospholipids, and salts; Lalonde and Calvert, 1979), *Frankia* broth (yeast extract, casein hydrolysate, salts and vitamins; Baker and Torrey, 1979), dilute Bennett "S" medium (casein hydrolysate, glucose, salts; Lechevalier et al., 1983), or defined media containing Tween 80, succinate, or pyruvate (Benson, 1982; Gauthier et al., 1981; Hafeez et al., 1984). In a time-course study of the outgrowth of frankiae from *Alnus incana* subsp. *rugosa* nodules, pyruvate was the best carbon source tested, followed by succinate and malate; propionate and acetate were less effective (Benson et al., 1984). Following plating, outgrowth may be observed microscopically

on inverted plates after 5 d for up to 8 weeks. The actual time involved depends to a great extent on the medium used. Some strains may require growth factors for initial outgrowth or for continued growth (Burggraaf, 1984; Normand and Lalonde, 1982; Quispel et al., 1983). However, such requirements are not universal and may reflect the composition of the medium used. Only one report of the isolation of *Frankia* strains using phenol-treated rhizosphere soil and the sucrose density technique exists (Baker and O'Keefe, 1984). Otherwise, isolations direct from the soil have not been reported.

Maintenance procedures

Depending on the strain used, cultures can be transferred as often as every 2 d for relatively fast-growing strains for up to every 4–6 months with storage at room temperature. A variety of media has been used for this purpose; liquid media used for routine cultivation are suitable for long-term on-the-shelf storage. For longer term storage and archival purposes, strains can be stored as heavy suspensions in 10% glycerol and frozen at −20°C or −80°C; −80°C is more effective for some strains. Upon thawing, glycerol should be removed with several washes of fresh medium as it inhibits growth of many strains. Outgrowth is usually rapid. Long-term preservation by lyophilization from broth or by storage in sterile soil also appears satisfactory. Nodules may be stored at −20°C for up to five or more years without loss of infectivity.

Differentiation of the genus *Frankia* from other genera

A proposed definition of the genus *Frankia* is essentially as proposed by Lechevalier and Lechevalier (1984):

1. Actinomycetic, nitrogen-fixing, root-nodule-forming endosymbionts or endoparasites that have been grown in pure culture *in vitro* and that:
   (a) induce effective (nitrogen-fixing) or ineffective (non-nitrogen-fixing) root nodules on a host plant and may be re-isolated from within the nodules of that plant; and
   (b) produce sporangia containing nonmotile spores in submerged liquid culture, and may also form vesicles.
2. Free-living actinomycetes having no known nodule-forming or nitrogen-fixing capacity, but that show the morphology described in 1(b) above.

List of species of the genus *Frankia*

1. **Frankia alni** (Woronin 1866) Von Tubeuf 1895, 118^{AL} (*Schinzia alni* Woronin 1866, 6)

al′ni. L. gen. n. *alni* of alder, the original source of isolation.

This is the only species designated in the genus; all other species proposed previously by Becking (1970) have been shown not to correspond to later descriptions of the genomic species (Akimov and Dobritsa, 1992; Akimov et al., 1991; An et al., 1983, 1985; Bloom et al., 1989; Fernandez et al., 1989; Lumini et al., 1996). Hence, the only species still valid is the first ever described that corresponds to the one described by Woronin (1866) as present in the roots of alder and shown later by Fernandez et al. (1989) to correspond to the numerically dominant group of strains infective on *Alnus*.

Aerial hyphae, chalky white, 0.5–1.2 µm in diameter.

There are probably about 20 genomic species among the isolates described so far and a similar number of unisolated strains not considering phyletic neighbors living in the soil (Normand and Chapelon, 1997), the rhizosphere of various plants, or other environments. However, given their slow growth rates and their tedious growth requirements, it is likely that a rigorous species designation is still a long way in the future. However, 16S rRNA gene sequence characterization work continues to be carried out (Clawson et al., 1998; Huguet et al., 2001; Jeong and Myrold, 1999; Lumini and Bosco, 1999; Navarro et al., 1999; Ritchie and Myrold, 1999a; Simonet et al., 1999; Wolters et al., 1997) and will be correlated with ecological work.

Source: root nodules of host plants (may also be found in soil).

DNA G+C content (mol%): 72.8 [as determined by complete genome sequencing (Normand et al., 2007b); see the Genoscope website for details (http://www.genoscope.cns.fr/externe/English/Projets/Projet_HF/HF.html)].

Type strain: since the publication of the Approved Lists of Bacterial Names, several strains of *Frankia alni* have been isolated. However, no type strain has been designated. The first strain isolated was HFPCpI1 (Callaham et al., 1978); it was deposited in the ATCC but, as is the case with several of the slow-growing *Frankia* strains, it could not be revived (although it is still available from diverse laboratories) and is no longer available there. Another strain, AvcI1 is available from the ATCC, but this strain has not been studied in detail. For these reasons, another strain, ACN14a isolated from *Alnus crispa* growing in Tadoussac (Normand and Lalonde, 1982), that has only two substitutions in the 16S rRNA gene (Normand et al., 1996) relative to HFPCpI1 has been widely distributed in different laboratories, and was chosen for genome sequencing.

Sequence accession nos: M88466 (16S rRNA gene; *Frankia alni* strain ACN14a), CT573213 (genome; *Frankia alni* strain ACN14a), CP000249 (genome; *Frankia* sp. strain HFPCcI3), and CP000820 (genome; *Frankia* sp. strain EAN1pec).

Family II. **Acidothermaceae** Rainey, Ward-Rainey and Stackebrandt 1997, 487[VP]

Philippe Normand, Alison Berry and David R. Benson

A.ci.do.ther.ma.ce′a.e. N.L. masc. n. *Acidothermus* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Acidothermaceae* the *Acidothermus* family.

Rainey, Ward-Rainey and Stackebrandt (in Stackebrandt et al., 1997) created the one-genus family *Acidothermaceae*, which contains only the type genus *Acidothermus* (Mohagheghi et al., 1986). As its name implies, it grows in hot acid springs. Phylogenetic analyses have shown that members of the family are the closest neighbors to members of the genus *Frankia* (Normand et al., 1996).

Type genus: **Acidothermus** Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442[VP].

Genus I. **Acidothermus** Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442[VP]

Philippe Normand, Alison Berry and David R. Benson

A.ci.do.ther′mus. L. adj. *acidus* sour, acid; Gr. adj. *thermos* hot; N.L. masc. n. *Acidothermus* acid and hot (loving).

Slender rods and filaments, 0.4 × 5–20 µm, with rounded ends (Figure 107). No endospores are formed. No flagella have been reported (Figure 108) and no motility has been observed, although the genome of *Acidothermus cellulolyticus* contains coding sequences for a flagellar apparatus (Barabote et al., 2009). **Gram-stain-variable**, but generally Gram-stain-negative. Thin sections show no outer cell membranes. The main constituents of purified cell walls are DAP, glucosamine, muramic acid, serine, and alanine. On LPBM mineral salts agar (Mohagheghi et al., 1986), colonies are creamy white, smooth, circular, entire, and 1–3 mm in diameter. In liquid culture, moderate turbidity is observed and cells may tend to flocculate and sediment out after 3 d. Obligate aerobes, prototrophic; grow

on several carbon sources including d-glucose, cellobiose, and **cellulose**. **Thermophilic** with optimal temperature of 55°C (range 37–70°C) and acidophilic with **optimal pH of 5.5** (pH range 3–7). Isolated from 55–60°C acidic water and mud samples in Yellowstone National Park in the course of a screening program to obtain thermostable cellulases. Cells may be stored in 20% (v/v) glycerol in LPBM medium at −80°C, and thawed on ice.

DNA G+C content (mol%): 66.9 (determined by complete genome sequencing).

Type species: **Acidothermus cellulolyticus** Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442[VP].

List of species of the genus *Acidothermus*

1. **Acidothermus cellulolyticus** Mohagheghi, Grohmann, Himmel, Leighton and Updegraff 1986, 442[VP]

cell.u.lo.ly′ti.cus. N.L. n. *cellulosum* cellulose; N.L. masc. adj. *lyticus* (from Gr. masc. adj. *lutikos*) able to loosen, able to dissolve; N.L. masc. adj. *cellulolyticus* cellulose-dissolving.

Morphology is as described for the genus. Grows on D-glucose, cellobiose, cellulose, xylan, D-galactose, maltose, sucrose, raffinose, D-mannose, D-mannitol, or D-sorbitol as sole carbon and energy sources. Grows on Casamino acids (0.1%) plus tryptone (0.1%); no growth is observed on nutrient broth, acetate, lactate, citrate, or pectin. Citrate and acetate are inhibitory at 0.01 M. Resistant to penicillin G at 100 μg/ml; sensitive to vancomycin and lysozyme. Catalase-positive. Does not contain polyamines (Hamana et al., 1991). Actively digests cellulose. Contains several genes for cellulose degradation (McCarter et al., 2002). Contains a gene for *shc* (squalene hopene cyclase) that may be involved in the ability to grow at high temperatures (Alloisio et al., 2005).

Source: isolated from 55–60°C acidic water and mud samples in Yellowstone National Park in the course of a screening program to obtain thermostable cellulases.

DNA G+C content (mol%): 66.9 (determined by complete genome sequencing).

Type strain: ATCC 43068, 11B.

Sequence accession nos: AJ007290 (16S rRNA gene sequence of ATCC 43068[T]); CP000481 (complete genome sequence of strain 11B[T]).

Family III. **Cryptosporangiaceae** Zhi, Li and Stackebrandt 2009, 596[VP]

Peter Kämpfer

Cryp.to.spo.ran.gi.a.ce′a.e. N.L. neut. n. *Cryptosporangium* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Cryptosporangiaceae* the *Cryptosporangium* family.

The delineation of the order is based on 16S rRNA gene sequence analysis and contains only the genus *Cryptosporangium* (Tamura et al., 1998). The pattern of 16S rRNA signatures consists of nucleotides at positions 195 (U), 196 (C), 601:637 (A–U), 602:636 (C–G), 841 (U), 952:1229 (C–G), 986:1219 (A–U), 1042 (U), 1059:1198 (U–A), 1251 (G), and 1003:1037 (A–C) according to Zhi et al. (2009). Phenotypic characters are that of the genus *Cryptosporangium*.

Members of the family are Gram-stain-positive, non-acid-fast, aerobic organisms with branching hyphae. The sporangia and aerial mycelia aggregate, and sporangiospores show motility when they are suspended in water. Strictly aerobic. Cell walls contain glutamic acid, glucosamine, glycine, alanine, and *meso*-diaminopimelic acid, with peptidoglycan type A1γ according to Schleifer and Kandler (1972). Glucose and acofriose are detected as whole-cell sugars. Major menaquinone is MK-9(H_6); small amounts of MK-9(H_4) and 9(H_8) are also present. Phosphatidylethanolamine and phosphatidylinositol are present as diagnostic phospholipids. The acyl type of cell wall polysaccharides is acetyl.

Type species: **Cryptosporangium** Tamura, Hayakawa and Hatano 1998, 1003[VP].

Genus I. **Cryptosporangium** Tamura, Hayakawa and Hatano 1998, 1003[VP]

Philippe Normand and David R. Benson

Cryp.to.spo.ran′gi.um. Gr. adj. *kruptos* hidden; N.L. n. *sporangium* [from Gr. n. *spora* a seed (and in biology a spore), and Gr. n. *angeion* (Latin transliteration *angium*) vessel], sporangium; N.L. neut. n. *Cryptosporangium* an organism with sporangia (spore containing vessels) covered or hidden by mycelium.

Gram-stain-positive, non-acid-fast, aerobic organisms with branching hyphae. Non-fragmentary substrate mycelia are present. The sporangia and aerial mycelia aggregate (Figure 109) and **sporangiospores show motility** when they are suspended in water. Morphology of a 2-week-old culture grown on inorganic salts-starch agar shows the presence of aerial mycelia. Strictly aerobic. Good growth occurs at 20–25°C. The organism shows good growth on oatmeal agar, inorganic salts-starch agar, and peptone-yeast extract iron agar. In general, the vegetative mycelia are yellow to orange and the aerial mycelia are white. Cell walls contain glutamic acid, glucosamine, glycine, alanine, and *meso*-DAP. Glucose and acofriose (3-*O*-methyl-rhamnose) are detected as whole-cell sugars. Major cellular fatty acids are $C_{17:1}$, $C_{18:1}$, and $C_{16:0}$ iso. The major menaquinone is MK-9(H_6); small amounts of MK-9(H_4) and MK-9(H_8) are also present. Phosphatidylethanolamine and phosphatidylinositol are present as diagnostic phospholipids. The acyl-type of the cell wall polysaccharides is acetyl (Tamura et al., 1998). Isolated from soil.

DNA G+C content (mol%): 70.

Type species: **Cryptosporangium arvum** Tamura, Hayakawa and Hatano 1998, 1003[VP].

FIGURE 109. Light micrograph (a) and scanning electron micrographs (b–d) of *Cryptosporangium arvum* YU 629-21[T] grown on humic acid-vitamin agar for 14 d at 28°C. Bars: (b) = 50 μm; (c) = 10 μm; (d) = 5 μm. The sporangia are multilocular, 3–7 μm in diameter, hidden under the hyphal mats (hence the genus name) and contain motile spores (Tamura et al., 1998). (Reprinted with permission from Tamura et al. 1998. Int. J. Syst. Bacteriol. *48*: 995–1005.)

Further descriptive information

The genus was created by Tamura et al. (1998) to accommodate soil isolates with a unique morphology and physiology and was composed of two species, *Cryptosporangium arvum* and *Cryptosporangium japonicum*. Two other species, comprising isolates initially described as "*Actinoplanes minutisporangius*" by Ruan et al. (1986) and "*Actinoplanes aurantiacus*", were added to the genus and renamed *Cryptosporangium minutisporangium* comb. nov. and *Cryptosporangium aurantiacum* comb. nov., respectively.

Differentiation of the species of the genus *Cryptosporangium*

Differential characteristics of the four *Cryptosporangium* species are given in Table 54.

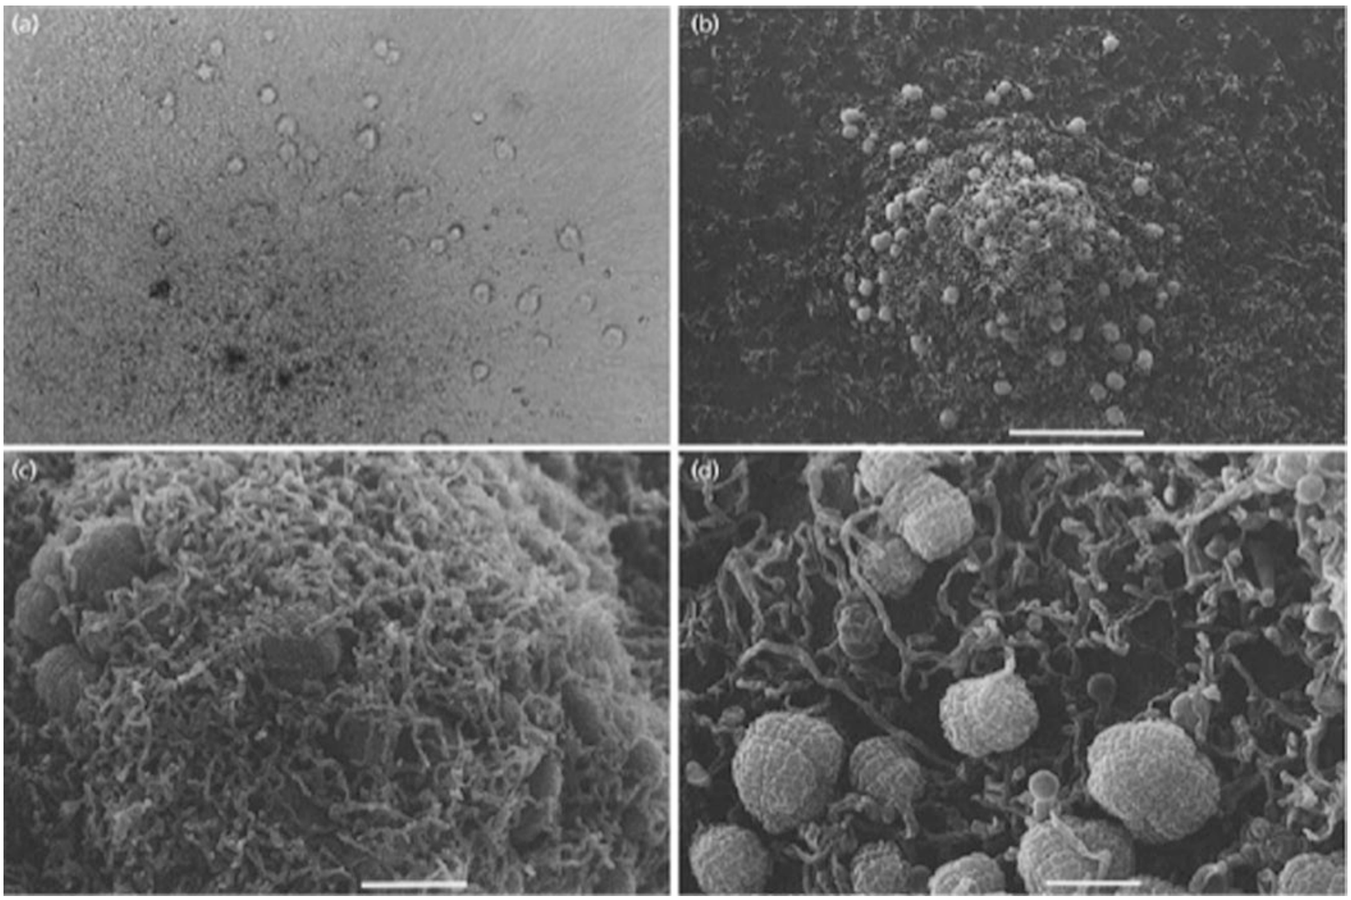

FIGURE 109. Light micrograph (a) and scanning electron micrographs (b–d) of *Cryptosporangium arvum* YU 629-21^T grown on humic acid-vitamin agar for 14 d at 28°C. [b]d, Positive or negative; w, weak.

List of species of the genus *Cryptosporangium*

1. **Cryptosporangium arvum** Tamura, Hayakawa and Hatano 1998, 1003[VP]

ar′vum. L. n. *arvum* arable land, pertaining to an isolate obtained from arable land.

Morphological, chemotaxonomic, and general characteristics are as given above for the genus. Pale red-brown soluble pigment is produced on tyrosine agar (ISP medium 7). Gelatin liquefaction is negative. Does not hydrolyze starch. Decomposes calcium malate. Coagulates milk. Xylose, glucose, inositol, raffinose, rhamnose, mannitol, sucrose, arabinose, glycerol, lactose, maltose, and mannose are utilized, but sorbitol and inulin are not. No growth at 37°C. Major cellular fatty acids are $C_{16:0}$ iso, $C_{18:1}$, $C_{17:1}$, and $C_{17:0}$.

Source: isolated from cultivated soil.

DNA G+C content (mol%): 70.1 (HPLC; Mesbah and Whitman, 1989).

Type strain: YU629-21, IFO 15965.

Sequence accession no. (16S rRNA gene): D85465.

2. **Cryptosporangium aurantiacum** (Ruan, Zhang and Jiang 1976) Tamura and Hatano 2001, 2124[VP] (Basonym: *Actinoplanes aurantiacus* Ruan, Zhang and Jiang 1976, 291.)

au.ran.ti.a′cum. N.L. neut. adj. *aurantiacum* gold- or orange-colored.

Morphological, chemotaxonomic, and general characteristics are as given for the genus. Red soluble pigment is produced on tyrosine agar (ISP medium 7). Starch is hydrolyzed. Gelatin and esculin are not hydrolyzed. Nitrate is reduced. No growth in 4% NaCl. Acid is produced from mannitol, melibiose, rhamnose, arabinose, galactose, mannose, glucose, and xylose, but not from erythritol, adonitol, maltose, lactose, sorbitol, methyl α-D-glucoside, dulcitol, or raffinose. Mannitol, melibiose, maltose, rhamnose, lactose, inositol, sorbitol, arabinose, galactose, mannose, glucose, xylose, and oxalate are utilized, but erythritol, adonitol, methyl α-D-glucoside, dulcitol, raffinose, succinate, malate, and citrate are not (Ruan et al., 1985; Tamura and Hatano, 2001).

Source: isolated from cultivated soil.

DNA G+C content (mol%): not determined.

Type strain: IFO 13967, JCM 3241, 71-C38.

Sequence accession no. (16S rRNA gene): AB047490.

3. **Cryptosporangium japonicum** Tamura, Hayakawa and Hatano 1998, 1003[VP]

ja.po′ni.cum. N.L. neut. adj. *japonicum* pertaining to Japan where the organisms were isolated.

Morphological, chemotaxonomic, and general characteristics are as given above for the genus. Pale red–brown

soluble pigment is produced on tyrosine agar (ISP medium 7). Gelatin liquefaction is negative. Does not hydrolyze starch. Decomposes calcium malate. Coagulates milk. Xylose, glucose, inositol, raffinose, rhamnose, mannitol, sucrose, fructose, arabinose, lactose, galactose, maltose, and mannose are utilized, but sorbitol and inulin are not. Grows at 37°C.

Source: isolated from cultivated soil.

DNA G+C content (mol%): 70.2–70.4 (HPLC; Mesbah and Whitman, 1989).

Type strain: YU636-3, IFO 15966.

Sequence accession no. (16S rRNA gene): D85466.

4. **Cryptosorangium minutisporangium** (Ruan, Lechevalier, Jiang and Lechevalier 1986) Tamura and Hatano 2001, 2123[VP] (Basonym: *Actinoplanes minutisporangius* Ruan, Lechevalier, Jiang and Lechevalier 1986, 573.)

mi.nu.ti.spo.ran′gi.um. L. adj. *minutus* little, small, minute; N.L. n. *sporangium* [from Gr. n. *spora* a seed (and in biology a spore), and Gr. n. *angeion* (Latin transliteration *angium*) vessel] sporangium; N.L. n. *minutisporangium* (nominative in apposition) the small sporangium.

The description is based on data compiled by Ruan et al. (1985) and Tamura and Hatano (2001). Morphological, chemotaxonomic, and general characteristics are as given previously for the genus (Tamura et al., 1998). Spores are motile. Brown to brownish-black substrate mycelium is produced. Hydrolyzes casein, hypoxanthine, urea, starch, and gelatin. Does not hydrolyze adenine or xanthine. Reduces nitrate to nitrite. Phosphatase is negative. Acetate, malate, pyruvate, succinate, and propionate are utilized, but lactate, benzoate, citrate, mucate, oxalate, and tartrate are not utilized. Acid is produced from arabinose, cellobiose, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, melibiose, methyl α-D-glucoside, rhamnose, salicin, sucrose, trehalose, and xylose, but not from adonitol, dulcitol, erythritol, raffinose, sorbitol, or methyl α-D-xyloside.

Source: isolated from soil.

DNA G+C content (mol%): 76 (HPLC; Mesbah and Whitman, 1989).

Type strain: IFO 15962, JCM 9458, ATCC 49415, LL-A-60.

Sequence accession no. (16S rRNA gene): AB048220.

Genus *Incertae sedis* I. **Fodinicola** Carlsohn, Groth, Saluz, Schumann and Stackebrandt 2008, 1534[VP]

Peter Kämpfer and Peter Schumann

Fo.di.ni′co.la. L. n. *fodina* a pit, mine; L. suff. *-cola* (from L. n. *incola*) dweller; N.L. masc. n. *Fodinicola* a mine dweller.

Cells are filamentous. A branched substrate mycelium and sparse to abundant white aerial mycelium is produced. The aerial hyphae break up into irregular rod-like elements. Gram-stain-positive. **Spores are not formed. Nonmotile. Aerobic metabolism.** Good growth is observed on complex organic media at 20–30°C. **Oxidase-negative, catalase-positive.** The cell-wall peptidoglycan contains *meso*-diaminopimelic acid (*meso*-A_2pm), alanine, glycine, and glutamic acid. The muramic acid in the peptidoglycan is *N*-acetylated. The **cell-wall sugars are xylose and minor amounts of an unknown compound**. The predominant menaquinones are **MK-9(H_4), MK-9(H_6), and MK-9(H_8).** The polar lipids comprise **diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and several unknown phospholipids and glycolipids** together with unknown ninhydrin-positive compounds. Mycolic acids are absent. The cellular fatty acid profile is characterized by the predominance of $C_{16:0}$ iso, 10-methyl-$C_{17:0}$, $C_{17:1}$ *cis*9, 10-methyl-$C_{18:0}$, and $C_{17:0}$. Based on 16S rRNA gene sequence similarities, the genus is closely related to the genus *Cryptosporangium* of the family *Cryptosporangiaceae*.

DNA G+C content (mol%): 65 (HPLC).

Type species: **Fodinicola feengrottensis** Carlsohn, Groth, Saluz Schumann and Stackebrandt 2008, 1534[VP].

Further descriptive information

Currently, the genus is represented by a single species, *Fodinicola feengrottensis*, which accommodates only one strain. 16S rRNA gene sequence comparisons showed that the type strain of *Fodinicola feengrottensis* shares 92.9–94.8% similarity with the type strains of species of the genus *Cryptosporangium*, and 93.9–94.5% similarity with the type strains of the genus *Sporichthya*. *Fodinicola feengrottensis* shares the 16S rRNA signature nucleotides of the families of the order *Frankiales* [as described for the *Frankineae* by Stackebrandt et al. (1997) with the exception of a U instead of a C at position 222 (Carlsohn et al., 2008)]. A maximum-likelihood tree is shown in Figure 110.

The peptidoglycan of *Fodinicola feengrottensis* contains *meso*-A_2pm, Ala, Gly, and Glu in a molar ratio of approximately 1.0:0.9:2.4:1.0. The presence of *meso*-A_2pm is shared by most genera of the order *Frankiales*, with the exception of *Sporichthya*, which contains LL-A_2pm (Carlsohn et al., 2008). The major menaquinones are MK-9(H_4), MK-9(H_6), and MK-9(H_8), in almost equal proportions, which is also in congruence with the quinones found in most of the closely related genera (Figure 110), with the exception of members of the genera *Nakamurella* and *Quadrisphaera*.

The major cellular fatty acids of the type strain of *Fodinicola feengrottensis* are $C_{16:0}$ iso (32.2%), 10-methyl-$C_{17:0}$ (10.7%), $C_{17:1}$ *cis*9 (8.9%), and 10-methyl-$C_{18:0}$ iso (8.5%); minor fatty acids are $C_{17:0}$ (7.4%), $C_{17:0}$ iso (5.8%), $C_{18:1}$ *cis*9 (4.8 %), 10-methyl-$C_{18:0}$ (4.7%), $C_{18:0}$ iso (3.2%), $C_{17:0}$ anteiso (3.0%), $C_{16:0}$ iso 2-OH (2.7%), and $C_{16:0}$ (2.6%). The phospholipids comprise diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and several unknown phospholipids

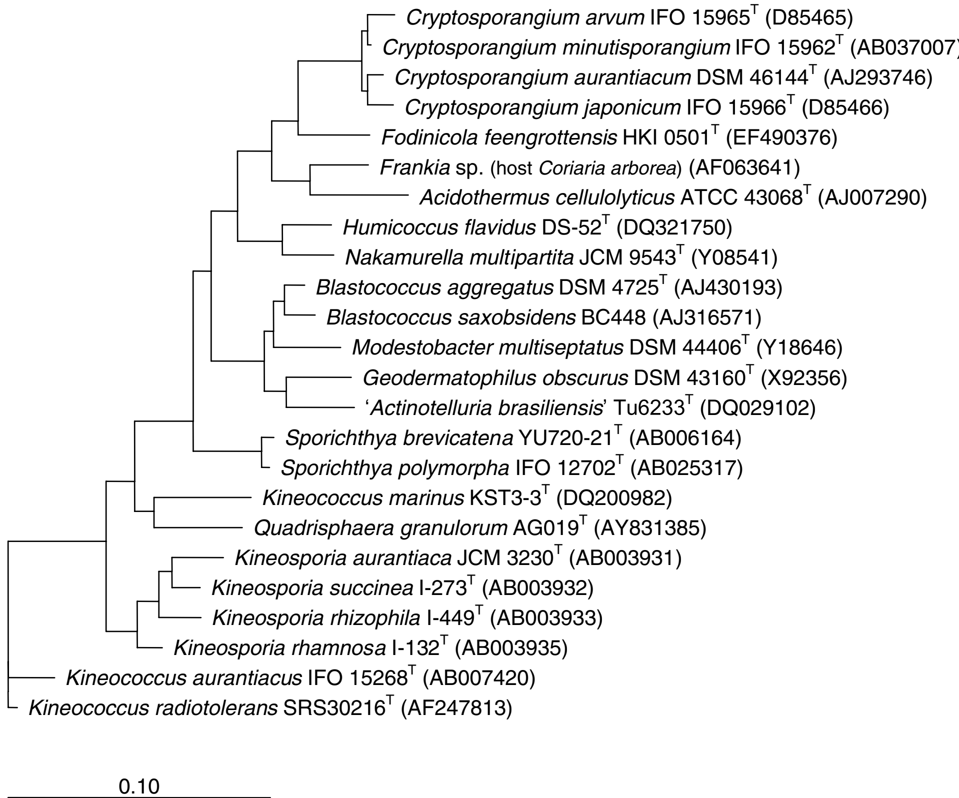

FIGURE 110. Phylogenetic analysis based on 16S rRNA gene sequences available from the EMBL database (accession numbers in parentheses), showing the position of *Fodinicola feengrottensis*. The phylogenetic tree was constructed using the ARB software package (version December 2007; Ludwig et al., 2004) and the corresponding SILVA SSURef 100 database (release August 2009; Pruesse et al., 2007). Tree building was performed using the maximum-likelihood method with fastDNAml (Olsen et al., 1994) and without filters. Bar = 0.10 nucleotide substitutions per nucleotide position.

and glycolipids, together with unknown ninhydrin-positive compounds (Carlsohn et al., 2008).

Enrichment and isolation procedures

Fodinicola feengrottensis grows readily in complex liquid or on solidified media, i.e., Bacto nutrient agar [(Difco) containing (g/l): Bacto beef extract, 3.0; Bacto peptone, 5.0; and Bacto agar, 15.0; pH 6.8] and tryptone soy agar (Oxoid). The type strain of *Fodinicola feengrottensis* was isolated from acidic and heavy metal-containing rocks in the "Barbara Grotto" of the Feengrotten medieval alum slate mine in Saalfeld, Thuringia, Germany, on starch-casein agar plates (Küster and Williams, 1964) supplemented with cycloheximide (50 mg/ml). The agar plates were incubated at 28°C for about 4 weeks. Subcultivation of the isolate was done on solidified organic medium 79 (Prauser and Falta, 1968; medium 426, http://www.dsmz.de/; 10.0 g glucose, 10.0 g peptone, 2.0 g casein peptone, 2.0 g yeast extract, 6.0 g NaCl, 15.0 g agar, 1000 ml distilled water; pH 7.8) and ISP 2 medium (Difco; Shirling and Gottlieb, 1966).

Maintenance procedures

Cultures of *Fodinicola feengrottensis* can be maintained by serial transfers on several complex media as listed above. Good growth is observed after 21 d of incubation at 28°C on casein agar plates (Küster and Williams, 1964), organic medium 79 (Prauser and Falta, 1968; medium 426, http://www.dsmz.de/), and ISP 2 medium (Difco; Shirling and Gottlieb, 1966).

Pure cultures can be preserved at 28°C as well-growing cultures in a mixture of organic medium 79 broth and glycerol medium that consisted of K_2HPO_4 (1.26%), KH_2PO_4 (0.36%), $MgSO_4$ (0.01%), sodium citrate (0.09%), $(NH_4)_2SO_4$ (0.18%), and glycerol (8.8%). Stock cultures of the novel isolate in liquid organic medium 79 supplemented with 5% DMSO can also be maintained in the vapor phase of liquid nitrogen.

Differentiation of the genus *Fodinicola* from other genera

Fodinicola feengrottensis forms branched substrate mycelium and sparse to abundant, short, white aerial hyphae that fragment into irregular rod-like elements. Spore chains and motility of the fragments, as reported for the coccoid to rod-shaped spores of the closely related *Sporichthya* strains (Lechevalier et al., 1968; Tamura et al., 1999), were not observed. Furthermore, the unique morphological properties of *Sporichthya* strains (lack of a substrate mycelium and the presence of a basal cell as a hold-fast in solid medium) can be useful to distinguish strain *Fodinicola feengrottensis* from members of that genus. Representatives

of the equally closely related genus *Cryptosporangium* (Tamura et al., 1998) can be also readily distinguished from *Fodinicola feengrottensis* because they produce spherical to irregularly shaped sporangia with spores that show motility when they are suspended in water. Differentiation from the only strain of the monospecific thermophilic genus *Acidothermus* is also possible on the basis of its typical morphological properties (slender rods, filaments).

List of species of the genus *Fodinicola*

1. **Fodinicola feengrottensis** Carlsohn, Groth, Saluz, Schumann and Stackebrandt 2008, 1534[VP]

fe.en.grot.ten′sis. N.L. masc. adj. *feengrottensis* pertaining to the Thuringian cave Feengrotten, the origin of the type strain.

Hyphal diameter is 0.35–0.52 μm. Diffusible pigments may be produced. Colonies are wrinkled and beige to orange in color. Good growth occurs between 20 and 28°C, but growth is not evident below 10°C or above 32°C. Grows well between pH 5.0 and 6.0, but does not grow at pH 4.0 or 8.0. Growth at pH 7.0 is delayed and reduced. A concentration of 1% NaCl in combination with organic medium 79 is tolerated, but 2% NaCl is not. Esculin, casein, gelatin, potato starch, and urea are hydrolyzed. Nitrate is not reduced to nitrite. Adenine, hypoxanthine, and tyrosine are not degraded. L-Arabinose, D-fructose, D-glucose (weakly), D-mannitol, raffinose, L-rhamnose, sucrose, and D-xylose are used as sole carbon sources for energy and growth, but *myo*-inositol and cellulose are not (all at 1%, w/v). Produces α-chymotrypsin (weakly), cystine arylamidase, leucine arylamidase, valine arylamidase, esterase (C4), esterase lipase (C8), α-galactosidase, β-galactosidase, *N*-acetyl-β-glucosaminidase, α-glucosidase, lipase (C14) (weakly), α-mannosidase, naphthol-AS-BI-phosphohydrolase, acid phosphatase, and alkaline phosphatase, but not α-fucosidase, β-glucosidase, or β-glucuronidase. Production of trypsin is variable (API ZYM tests). Susceptible to the following antibiotics (μg per disc): chloramphenicol (30), ciprofloxacin (5), imipenem (10), kanamycin sulfate (30), norfloxacin (10), novobiocin (5), oxytetracycline hydrochloride (30), streptomycin sulfate (10), sulfonamide (200), and vancomycin hydrochloride (30). Resistant to the following antibiotics (μg per disc, unless otherwise indicated): ampicillin (10), lincomycin hydrochloride (2), methicillin (5), nalidixic acid (30), penicillin G (10 IU), polymyxin B (300 IU), and rifampin (30).

Source: the type strain was isolated from acidic and heavy metal-containing rocks in the "Barbara Grotto" of the Feengrotten medieval alum slate mine in Saalfeld, Thuringia, Germany.

DNA G+C content (mol%): 65 (HPLC).

Type strain: HKI 0501, DSM 19247, JCM 14718.

Sequence accession no. (16S rRNA gene): EF490376.

Family IV. **Geodermatophilaceae** Normand 2006, 2277[VP] (Effective publication: Normand, Orso, Cournoyer, Jeannin, Chapelon, Dawson, Evtushenko and Misra 1996, 8.)

Philippe Normand and David R. Benson

Ge.o.der.ma.to.phi.la.ce′a.e. N.L. masc. n. *Geodermatophilus* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Geodermatophilaceae* the *Geodermatophilus* family.

Normand et al. (1996) created the family *Geodermatophilaceae*, which was confirmed the following year (Stackebrandt et al., 1997); however, no type genus was designated at that time. The family status has been formalized recently and a formal description has been published (Normand, 2006). As proposed, this family contains the type genus *Geodermatophilus* (Luedemann, 1968) found in soils, the genus *Blastococcus* (Ahrens and Moll, 1970) found in seawater, and the genus *Modestobacter* (Mevs et al., 2000) found in polar "soil". Characteristics of the three genera are given in Table 55. A common morphological feature of the three genera is **rudimentary hyphae** and common physiological features are modest growth requirements and the **ability to grow as a pioneer on exiguous substrates**. A 16S rRNA gene sequence signature pattern has been proposed consisting of nucleotides at positions 139:224 (C–G), 157:164 (A–U), 158:163 (A–U), 186:191 (C–G), 263 (G), 293:304 (G–U), 986:1219 (U–A), 987:1218 (A–U), 1059:1198 (U–A), and 1308:1329 (U–A) (Stackebrandt et al., 1997). A further signature of the *Geodermatophilaceae* would appear to be 5′-TGGGATAACTCCAAG**AAATT**GG-3′ at coordinates 122–143 of the 16S rRNA gene sequence of *Blastococcus aggregatus* DSM 4725^{T} (accession no. AJ430193) with the underlined bold "AA" and "TT" being diagnostic for the family, including a proposed species "*Actinotelluria brasiliensis*" (accession no. DQ029102; M. Bertazzo and others, unpublished). A second signature of the *Geodermatophilaceae* would appear to be 5′-GTCGGTAAC**G**CCCGAAGCCGGTGGC-3′ at coordinates 1385–1409 of the 16S rRNA gene sequence of *Geodermatophilus obscurus* (accession no. L40620) with the underlined bold "G" being diagnostic for the family.

Type genus: **Geodermatophilus** Luedemann 1968, 1857[AL].

TABLE 55. Characteristics of the three genera of the family *Geodermatophilaceae*[a]

Characteristic	*Geodermatophilus*	*Blastococcus*	*Modestobacter*
Morphology:

Genus I. **Geodermatophilus** Luedemann 1968, 1857[AL]

Philippe Normand and David R. Benson

Ge.o.der.ma.to.phi′lus. Gr. n. *ge* earth; Gr. n. *derma*, *atos* skin; Gr. adj. *philos* loving; N.L. masc. n. *Geodermatophilus* a group of microorganisms that live in the soil, yet that love the skin, by analogy to the genus *Dermatophilus*, the actinobacterial genus causing a skin disease, that has similar morphological features.

Morphology is similar to that of *Dermatophilus*, a group of actinobacteria that have **rudimentary hyphae** (Figure 111) that eventually develop into **complex sporangia** (Figure 112). *Geodermatophilus* strains have been isolated from relatively extreme environments such as desert or high altitude soils. They also appear to resist gamma irradiation and have been recovered from desert soils after exposure to 30 kGy, along with strains of *Deinococcus* that are more noted for radiation resistance (Rainey et al., 2005). They have been recovered during programs aimed at isolating bacteria, in particular motile ones (Hayakawa et al., 2000), that have atypical metabolic features such as **manganese-oxidizing ability**, and are frequently associated with "varnish" formation, the black to brown coatings found on rocks in a diverse range of environments (Hungate et al., 1987) and, more

surprisingly, in biofilm formation (Singh et al., 2003). Despite several trials, pathogenic lesions have not been produced by inoculation of *Geodermatophilus* isolates into rabbits (Gordon and Perrin, 1971). These trials had been attempted given the morphological and ontogenetic similarities with *Dermatophilus*. It is now known these morphological similarities constitute a case of convergent evolution of a few remarkable features rather than phylogenetic similarity.

DNA G+C content (mol%): 72.9–74.6.

Type species: **Geodermatophilus obscurus** Luedemann 1968, 1857[AL].

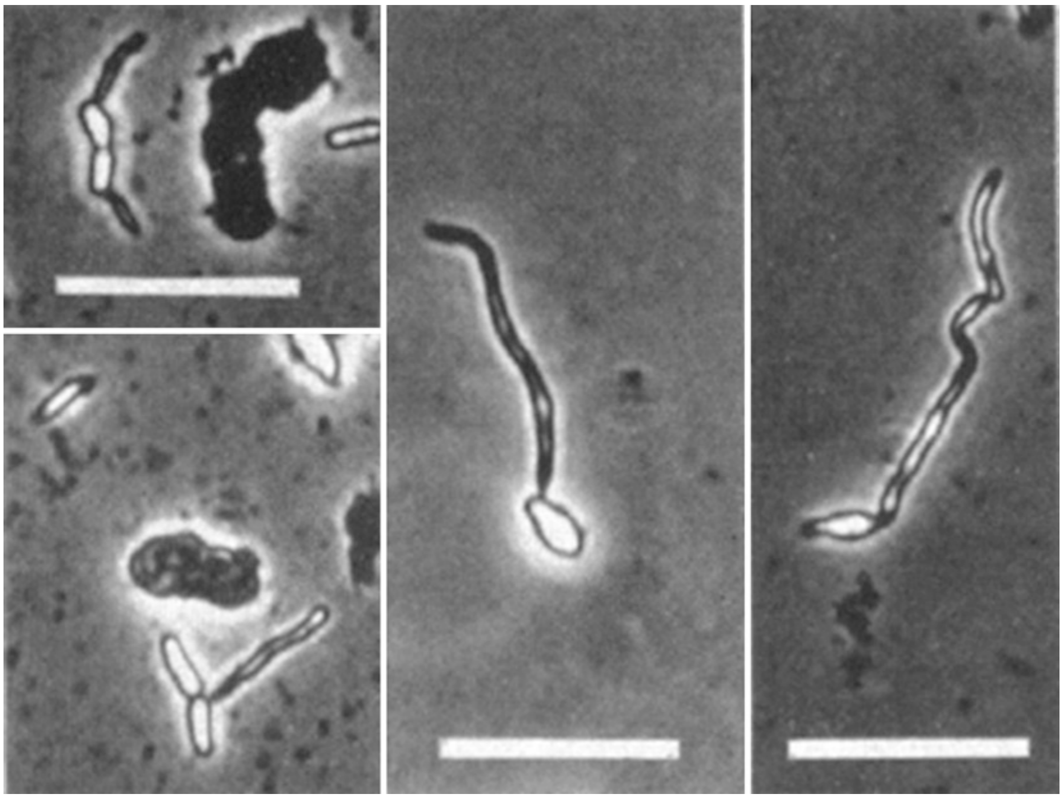

FIGURE 111. "*Geodermatophilus obscurus* subsp. *utahensis*" strain G-17 rudimentary hyphae in liquid cultures after 9–13 d (Luedemann, 1968). Bar = 1 µm. (Reprinted with permission from Luedemann, 1968. J. Bacteriol. *96:* 1848–1858.)

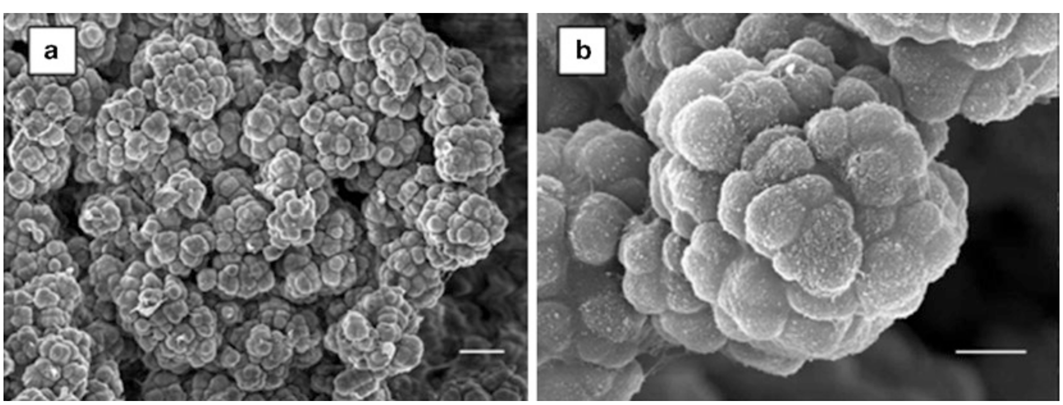

FIGURE 112. Multilocular sporangia of *Geodermatophilus obscurus* KCC A-0152^{T} (=ATCC 25078^{T}). Bars: (a) 5 µm; (b) 2 µm. (Photos courtesy of Shin-ichi Suzuki, Tanabe Seiyaku Co., Saitama, Japan.)

List of species of the genus *Geodermatophilus*

1. **Geodermatophilus obscurus** Luedemann 1968, 1857[AL]

ob.scur′us. L. masc. adj. *obscurus* dark, obscure, indistinct.

Pigmented. Gram-positive. Forms highly irregular tuber-shaped non-capsulated multilocular thalli. These structures contain highly irregular vibrioid or cuboid cells, 0.5–2.0 µm in diameter. Under favorable environmental conditions, the thalli will release individual non-motile cells. A proportion of these cells will develop into elliptical zoospores propelled by a terminal tuft of long flagella (Figure 113). Mycelium is rudimentary. No aerial mycelium is produced. Cell walls contain *meso*-DAP as well as glutamic acid, alanine, glucosamine and muramic acid. Aerobic. Chemoorganotrophic. Mesophilic. Thalli appear greenish-black and vary in size with the strain. Colonies after 30 d incubation at 28°C are flat, granular, dry, with a dank smell. Good growth on yeast extract-starch-sucrose-malt extract agar.

Source: the type strain was isolated from soil of the Amargosa Desert, Nevada, USA.

DNA G+C content (mol%): 72.9–74.6 (Luedemann and Fonseca, 1989).

FIGURE 113. "*Geodermatophilus obscurus* subsp. *everesti*" (16 h culture) with polar tuft of three flagella. Negatively stained with 0.02% potassium phosphotungstate (45,400×) (Ishiguro and Wolfe, 1970). (Reprinted with permission from Ishiguro and Wolfe, 1970. J. Bacteriol. *104*: 566–580.)

Type strain: ATCC 25078, DSM 43160, NBRC 13315, JCM 3152, NRRL B-3577, VKM Ac-658, CBS 237.69, IAM 14282, JCM 3152, KCC A-0152, NBRC 13315.

Sequence accession no. (16S rRNA): L40620.

Other organisms

Five subspecies (Ishiguro and Fletcher, 1975; Luedemann, 1968) have been proposed; discriminating features are given in Table 56.

1. **"Geodermatophilus obscurus subsp. obscurus"** Luedemann 1968, 1857

ob.scur′us. L. masc. adj. *obscurus* dark, obscure, indistinct.

Source: isolated from soil of the Amargosa Desert, Nevada, USA.

Type strain: ATCC 25078.

2. **"Geodermatophilus obscurus subsp. amargosae"** Luedemann 1968, 1857

a.mar.go′sae. N.L. gen. n. *amargosae* of the Amargosa Desert.

Source: isolated from soil of the Amargosa Desert, Nevada, USA.

Type strain: ATCC 25081.

3. **"Geodermatophilus obscurus subsp. utahensis"** Luedemann 1968, 1857

u.tah.en′sis. N.L. masc. adj. *utahenis* belonging to Utah (one of the United States).

Source: isolated from soil of Zion National Park, Utah, USA.

Type strain: ATCC 25079.

4. **"Geodermatophilus obscurus subsp. dictyosporus"** Luedemann 1968, 1858

dic.ty.o.spo′rus. Gr. n. *diktuon* a net; Gr. fem. n. *spora* a seed; N.L. n. *dyctiosporus* netted spores, referring to criss-crossings seen on spores.

Source: isolated from soil of Westgard Pass, California, USA.

Type strain: ATCC 25080.

5. **"Geodermatophilus obscurus subsp. everesti"** Ishiguro and Fletcher 1975, 106

ev.er.est′i. N.L. gen. n. *everesti* of Mount Everest, Nepal.

Source: isolated from West Ridge of Mount Everest at an elevation of 8300 m.

Type strain: 22-68.

Genus II. **Blastococcus** Ahrens and Moll 1970, 264[AL] emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257 emend. Lee 2006, 2394

Erko Stackebrandt and Peter Schumann

Blas.to.coc′cus. Gr. n. *blastos* bud, shoot; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Blastococcus* budding coccus.

Gram-stain-positive, coccoid, occurs singly or in pairs, **often reproducing by budding and multiple fission, giving rise to a variety of cell forms. Single cells may be motile rods and vibroid or non-motile cocci that tend to form aggregates. Strains may form motile zoospores.** Formation of buds on rods is common, but not universal. Membranous bodies, 1–4 per cell, which are linked to the cytoplasmic membrane, may be present. Oxidase-negative, catalase-positive, and aerobic; some strains may be microaerophilic. Strains from surfaces of marble and limestone utilize a broader spectrum of organic compounds than the only known marine strain. **Predominant fatty acids are $C_{16:0}$ iso, and, in some strains, $C_{16:1}$ iso, $C_{18:1}$ ω9*c*, $C_{17:1}$ ω8*c*, $C_{15:0}$ iso, and $C_{17:0}$. Peptidoglycan contains *meso*-DAP** as diagnostic diamino acid. **Predominant menaquinone is MK-9(H_4)**; MK-9 may also occur in high amounts. Polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine; phosphatidylcholine, phosphatidylethanolamine, and two unknown phospholipids may occur. Arabinose and galactose have been identified as whole-cell sugars in one species. Phylogenetically, a member of the family *Geodermatophilaceae*.

DNA G+C content (mol%): 72.3–74.

Type species: **Blastococcus aggregatus** Ahrens and Moll 1970, 264[AL] emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257.

Further descriptive information

The morphology of *Blastococcus aggregatus*, isolated from sediment of the Baltic Sea, is similar to that of *Geodermatophilus* as two forms occur: motile rods that multiply by budding and thallic aggregates of coccoid cells (Figure 114 and Figure 115). The original description of this species (Ahrens and Moll, 1970; in German) gives detailed information on morphological variations. The manifestation of the stages is influenced by environmental parameters: the formation of the motile rod stage is supported by low temperatures (5–10°C), low salt concentrations, and anaerobic conditions, whereas increased temperature and salt concentrations induce the formation of aggregates. Isolates from desert soil and altered stone surfaces from monuments and natural stones in the Mediterranean basin resemble members of the family *Geodermatophilaceae* morphologically (Figure 114 and Figure 115). Cells of *Blastococcus jejuensis* KST3-10[T] are coccoid and occur in pairs or are rod-shaped, flagellated, and motile (Figure 114 and Figure 115); only the rod-shaped cells show bud formation.

Phylogenetically, *Blastococcus* species (Eppard et al., 1996; Urzì et al., 2001), together with members of the genera *Geodermatophilus* and *Modestobacter*, constitute the family *Geodermatophilaceae* (Normand, 2006). Strains from arid environments are related to the genus *Geodermatophilus*, whereas those from the surface of calcareous stones and monuments, mainly from

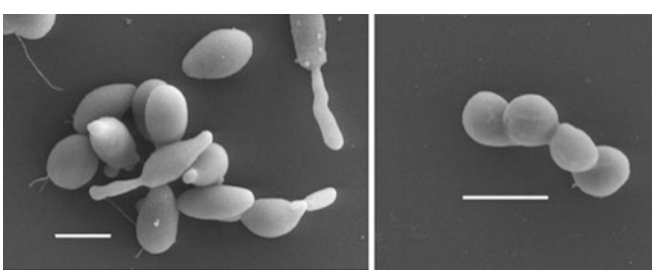

FIGURE 114. Electron micrographs of (left) *Blastococcus aggregatus* DSM 4725[T] and (right) *Blastococcus saxobsidens* BC444[T] showing single cells, pairs and tetrads. (Reprinted with permission from Urzì et al., 2004b. Int. J. Syst. Evol. Microbiol. *54*: 253–259.)

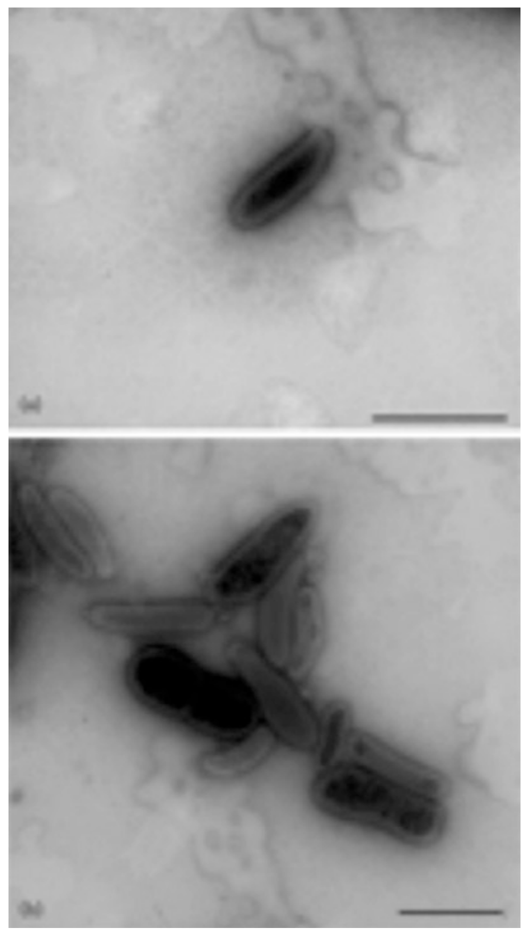

FIGURE 115. Transmission electron micrographs of *Blastococcus jejuensis* KST3-10[T] grown on YE-SW agar for 3 d at 30°C. (top) Rod-shaped cell with flagella; (bottom) coccoid cells in pairs and rod-shaped cells showing bud formation. Bars = 1.0 µm. (Reprinted with permission from Lee, 2006. Int. J. Syst. Evol. Microbiol. *56*: 2391–2396.)

Italy and Spain, exposed to rainy winters and hot, dry summers belong to the genera *Modestobacter* and *Blastococcus*. The type strain of *Blastococcus aggregatus* shared only a few characteristics in common with the stone surface strains such as the formation of pink–orange colonies, aerobic metabolism, and the presence of *meso*-DAP as diagnostic diamino acid and MK-9(H_4) as predominant menaquinone. Differences observed in the fatty acid composition and physiological properties led to the description of a novel species, *Blastococcus saxobsidens*, for a subset of these novel isolates. Strains of *Blastococcus saxobsidens* do not grow in concentrations of NaCl above 3%; the influence of external parameters on cell morphology has not been investigated for strains of this species (Urzì et al., 2004b). The third species, *Blastococcus jejuensis* (Lee, 2006), differs from the other two species of the genus by the absence of phosphatidylglycerol and the presence of phosphatidylcholine and phosphatidylmethylethanolamine; it differs from *Blastococcus aggregatus* in terms of the relative amounts of $C_{16:1}$ iso, $C_{17:1}$ ω8*c*, $C_{18:1}$ ω9*c*, and $C_{18:0}$ fatty acids (Urzì et al., 2004b) and from *Blastococcus saxobsidens* in possessing $C_{18:0}$ and $C_{12:0}$, and in terms of the relative amounts of $C_{16:0}$, $C_{17:1}$ ω8*c*, and $C_{18:1}$ ω9*c*.

Physiological properties that differentiate the three species are given in Table 57.

Enrichment and isolation procedures

Blastococcus aggregatus was isolated in peptone-yeast medium (5 g/l peptone, 1 g/l yeast extract, 0.1 g/l $FePO_4$ in 1 l tap water, pH 7.2) plus 0.8% NaCl. It grew as tiny, shiny, pink-colored colonies within 5 d at 20°C at NaCl concentrations between 0.8 and 2.4%. After 21 d, colonies were 1 mm in diameter and pink in color. Their surface showed an orange peel appearance under a microscope at low magnification.

For the isolation of strains and relatives of *Blastococcus saxobsidens*, material scratched from altered stones and monuments was dilution-plated on Bunt and Rovira medium (Bunt and Rovira, 1955), modified by the addition of 0.5% glucose, 0.5% NaCl and 0.03% Na_2CO_3, pH 8.6 (medium BRII) plus actidion (50 mg/l) and maintained in Luedemann medium (Luedemann, 1968). Various amounts (100 mg to 1 g) of rock samples or powder from scraped surfaces were taken depending on the artistic importance of the sampled surface (monument, building, or rock from quarry). In the laboratory, each sample was ground to a powder in a sterile mortar, suspended (ratio 1:10, w/v) in physiological saline (0.85% NaCl) supplemented with 0.001% (w/v) Tween 80, and vortexed for 60 min. Incubation was carried out at 28°C.

Blastococcus jejuensis KST3-10^T was isolated from sediment samples taken at a depth of 1 m from surface water of Gwakji beach on Jeju Island, Republic of Korea. Samples were placed into sterilized 50 ml Falcon tubes containing seawater. For bacterial isolation, 1 g sand sediment was placed into a sterile plastic tube containing 9 ml sterile distilled water and then mixed in a tube rotator for 30 min at a moderate speed. Aliquots (100 μl) of the serial dilution of the samples were transferred onto SC-SW

TABLE 57. Differentiation between the type strains of *Blastococcus* species using morphological and physiological parameters[a,b]

Characteristic	*B. aggregatus*	*B. saxobsidens*	*B. jejuensis*

[b]Data from Urzì et al. (2004b) and Lee (2006).

agar plates supplemented with 60% (v/v) sterilized natural seawater. SC-SW agar comprised 1% soluble starch, 0.03% casein, 0.2% KNO_3, 0.2% NaCl, 0.002% $CaCO_3$, 0.005% $MgSO_4·7H_2O$, 0.001% $FeSO_4·7H_2O$, and 1.8% agar in 60% sterilized natural seawater and 40% distilled water (pH 7.2).

Maintenance procedures

Strains have been stored for some weeks on slants at 4°C and in 20% (w/v) glycerol suspensions at −20°C and −80°C. Long-term preservation methods include freeze-drying in skim milk and storage in liquid nitrogen at −196°C. *Blastococcus jejuensis* KST3-10^T was maintained on ISP 2 medium (Shirling and Gottlieb, 1966) supplemented with 60% sterilized natural seawater (YE-SW agar) and in a 20% (v/v) glycerol suspension supplemented with 60% (v/v) sterilized natural seawater at −20°C and −80°C.

Taxonomic comments

At the time of the first circumscription of the novel taxon "*Blastococcus*", the authors refrained from assigning strain B15 to a genus. They stated that in case strain B15 should merit species status, the name "*Blastococcus aggregatus*" should be created. Despite the lack of a proper description, *Blastococcus aggregatus* was placed on the Approved Lists of Bacterial Names (Skerman et al., 1980). The subsequent placement of the genus *Blastococcus* in the family *Geodermatophilaceae* was based on phylogenetic analysis of the type strains of *Blastococcus aggregatus* and *Geodermatophilus obscurus* as well as of two *Frankia* strains (Hahn et al., 1989). This study followed a phylogenetic survey of the family *Dermatophilaceae* (Stackebrandt et al., 1997), showing the separate position of the genera *Dermatophilus* and *Geodermatophilus* within the tree of members of the *Actinomycetales*. The taxonomic status of *Blastococcus* was confirmed with the description of the suborder *Frankineae* Stackebrandt et al. 1997, embracing the families *Frankiaceae* Becking 1970, *Microsphaeraceae* Rainey et al. 1997, *Sporichthyaceae* Rainey et al. 1997, *Acidothermaceae* Rainey et al. 1997 and *Geodermatophilaceae* Normand et al. 1996, Normand 2006. In the taxonomic roadmap to the present volume, the suborder *Frankineae* has been elevated to order status as *Frankiales*, in the class *Actinobacteria*. The family *Geodermatophilaceae* consists of the genera *Geodermatophilus*, *Blastococcus*, and *Modestobacter*. The latter genus is represented by beige-, pink-, and brown-pigmented organisms of multiple irregular shapes with motile buds (Mevs et al., 2000; Reddy et al., 2007).

Until recently, the description of *Blastococcus* has been based heavily on morphological properties of a single strain isolated from the Baltic Sea (Ahrens and Moll, 1970). Recently, many more strains from terrestrial, mainly arid environments have been reported (Eppard et al., 1996; Urzì et al., 2001, 2004b) and taxonomic studies pointed to the presence of a second species of *Blastococcus*. In due course, *Blastococcus saxobsidens* was described and the description of the type strain of *Blastococcus aggregatus* was also extended and brought up to present description standards (Urzì et al., 2004b).

Contradictory results have been published concerning the phylogenetic position of members of the order *Frankiales*. In the 16S rRNA gene dendrogram of Normand et al. (1996), the families *Frankiaceae* and *Geodermatophilaceae* were separated by members of the *Actinoplanes* group. The intra-class relatedness of *Actinobacteria* depicted by Stackebrandt et al. (1997) sees members of the *Frankiales* clustering together to the exclusion of *Actinoplanes* and related taxa of the *Micromonosporaceae*. A more recent dendrogram (Maszenan et al., 2005) supports the phylogenetic separation of the families, although the topology is in conflict with the higher taxonomic order. Obviously, the number of genera and species within the class *Actinobacteria* has now grown so large that the selection of a subset of reference organisms (number and affiliation) in the analysis, together with the different algorithms applied, will have a significant effect on the topology of phylogenetic trees. It is, however, encouraging that the relationship between members of the genera *Blastococcus* and *Geodermatophilus* remains unchanged (Lee, 2006; Mevs et al., 2000).

The genomic homogeneity of strains of *Blastococcus saxobsidens* has been demonstrated by RiboPrint analysis (Bruce, 1996; Urzì et al., 2004b) using the restriction enzymes *Pvu*II and *Pst*I (Figure 116).

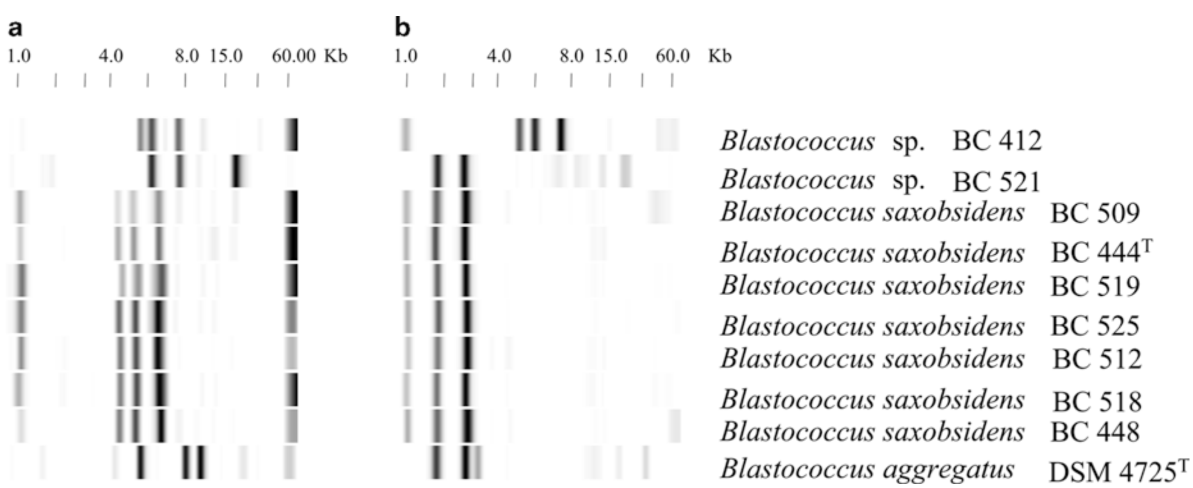

FIGURE 116. RiboPrint patterns of strains of *Blastococcus saxobsidens*, *Blastococcus aggregatus* DSM 4725^T and two phylogenetically moderately related *Blastococcus* isolates, generated with *Pvu*II (a) and *Pst*I (b).

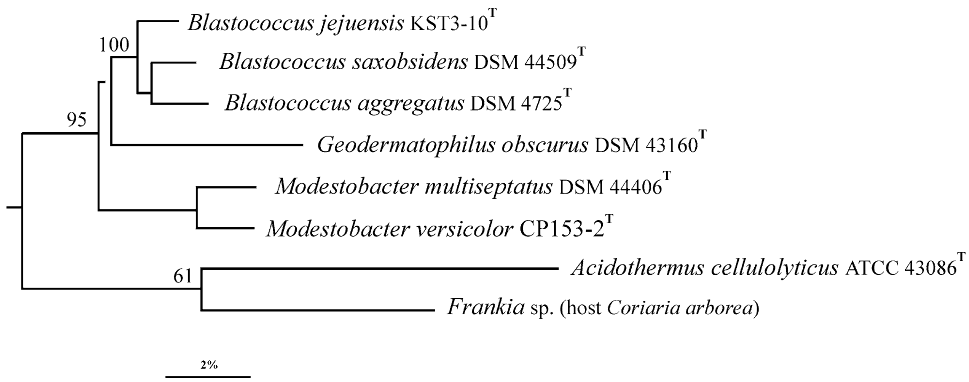

FIGURE 117. Distance matrix (DeSoete, 1983; Jukes and Cantor, 1969) 16S rRNA gene sequence dendrogram displaying the relatedness of *Blastococcus*-like organisms to the type strains of species of *Geodermatophilus*, *Modestobacter*, and *Blastococcus*. The sequences of members of the *Actinoplanaceae* served as an outside reference. Bootstrap values (Felsenstein, 1985) (1000 replicates, >70% confidence) are indicated at respective nodes. Sequence accession numbers used are as follows: *Blastococcus aggregatus* DSM 4725^T, AJ430193; *Blastococcus jejuensis* KST3-10^T, DQ200983; *Blastococcus saxobsidens* DSM 44509^T, AJ296061; *Geodermatophilus obscurus* DSM 43160^T, X92356; *Modestobacter multiseptatus* DSM 44406^T, Y18646; *Modestobacter versicolor* CP153-2^T, AJ871304; *Acidothermus cellulolyticus* ATCC 43068^T, AJ007290; *Frankia* sp. (host *Coriaria arborea*), AF063641. Bar = 2% sequence difference.

In addition to strains of *Blastococcus aggregatus* and *Blastococcus saxobsidens*, phylogenetic analysis of strains from rocks and ornaments pointed to the existence of two additional lineages within the genus, each represented by a single strain only [BC412 (=DSM 44517) and BC521 (=DSM 44518)]. These two strains (Figure 117), which shared 98.2% 16S rRNA gene sequence similarity, were not included in any *Blastococcus* species because of low DNA–DNA hybridization values with *Blastococcus saxobsidens* BC444^T (39% similarity with strain BC412 and 50% similarity with strain BC521). All three isolates were clearly unrelated to *Blastococcus aggregatus* DSM 4725^T (25–37% similarity). Based upon genomic differences, i.e. variations in ribopatterns (Figure 116) and morphological differences, i.e., formation of elongated cells, production of germ tubes and long filaments, as well as the formation of small motile zoospores, the single-strain taxa would merit a formal description. The rationale for refraining from describing novel species was based on the finding that *Blastococcus saxobsidens* showed a significant number of variable and weak physiological reactions. This indicates that the intraspecies metabolic diversity is higher than that expressed by the type strain.

Two 16S rRNA gene sequence oligonucleotides for differentiating members of the family *Geodermatophilaceae* have been described (Urzì et al., 2004a). One identifies members of the genus *Modestobacter* (TTCGCCGCTAGGGCA, position 96 of the *Escherichia coli* sequence), whereas the other is specific for members of the genera *Geodermatophilus* and *Blastococcus* (CCATCCCCAGCCGGAAACC, position 211; although not tested on *Blastococcus jejuensis*, the probe should also detect the type strain KST3-10^T). Differentiation between members of the latter two genera can be achieved on the basis of differences in pigmentation of colonies: those of *Geodermatophilus* are brown to black, whereas those of *Blastococcus* are pink to pinkish-orange (see Table 58). These oligonucleotides have been used in the affiliation of strains isolated from stone monuments (Urzì et al., 2001, 2004a)

Differentiation of the genus *Blastococcus* from other genera

Table 58 indicates diagnostic properties that are useful in the differentiation of the three genera of the family *Geodermatophilaceae*. A combination of the phylogenetic position of an isolate compared to the type strains of the family, together with colony pigmentation will allow assignment of species to genera.

Further reading

Akkermans, A.D.L., D. Hahn and D.D. Baker. 1992. The family *Frankiaceae*. *In* The Prokaryotes (edited by Balows, Trüper, Dworkin, Harder and Schleifer), Springer, New York, pp. 1069–1984.

Differentiation of the species of the genus *Blastococcus*

Data that differentiate the three *Blastococcus* species are given in Table 57. Results for additional strains of *Blastococcus saxobsidens* have been reported by Urzì et al. (2004b). All three type strains are positive for leucine arylamidase and glucose assimilation. *Blastococcus aggregatus* and *Blastococcus saxobsidens* are positive or weakly positive for esterase (C4), esterase (C8), Tween 40, Tween 80, and utilization of D-ribose and methyl succinate, whereas *Blastococcus jejuensis* KST3-10^T is negative for these properties. Biolog GP2 microplates give positive results for strain KST3-10^T and negative results for the type strains of *Blastococcus aggregatus* and *Blastococcus saxobsidens* for utilization of mannan, *N*-acetyl-β-D-mannosamine, amygdalin, cellobiose, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, *myo*-inositol, maltose, D-mannitol, D-mannose, melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl-D-glucoside, palatinose, L-rhamnose, sedoheptulosan, D-sorbitol, sucrose, D-tagatose, turanose, xylitol, γ-hydroxybutyric acid, α-ketovaleric acid, D-lactic acid methyl ester, L-malic acid, succinic acid, L-asparagine, putrescine, 2,3-butanediol, and D-glucose 6-phosphate. All strains are negative for nitrate reduction, glucose fermentation, urease, and utilization of the majority of substrates in the Biolog GN substrate panel.

TABLE 58. Comparative phenotypic characteristics of members of the family *Geodermatophilaceae*[a]

Phenotypic characteristic	*Blastococcus*	*Geodermatophilus*	*Modestobacter*
Cell shape	Cocci, rods, vibrios	Cocci to cuboids, rods	Cocci, rods
Aggregation	v	+	+
Bud formation	v	v	+
Motility	v	v	+[d], v[e]
Colony pigmentation	Pink, pinkish-orange	Brown, black	Pale pink[d]/brown, pink, white[e]

List of species of the genus *Blastococcus*

1. **Blastococcus aggregatus** Ahrens and Moll 1970, 264[AL] emend. Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 257

ag.gre.ga′tus. L. masc. part. adj. *aggregatus* added to, joined together, referring to the tendency to form coccoid aggregates.

Gram-positive, highly irregular vibroid or rod-shaped cells occurring singly or in three-dimensional coccoid aggregates. The manifestation of these stages is influenced by environmental conditions; low salt concentrations, temperatures of 5–10°C, and microaerophilic conditions favor the motile rod stage. Single cells are either motile vibroids (0.3–1.5 × 0.4–3.0 μm) or rods or ellipsoid (1.2–1.5 × 1.5–3.0 μm). Rods are often separated by disk-like septa. These motile or non-motile rods carry 1–6 vibrioform buds, attached by a tapered pole onto the mother cell. Increased temperature and salt concentrations induce the formation of non-motile coccoid aggregates (1.2–2.5 μm in diameter), appearing as linear, band-like, or column-like three-dimensional forms. Larger aggregates (1 mm in diameter) are separated by rectangular and/or radial partitions. Cell types of different sizes occur mostly side by side. After 5 d on peptone-yeast extract agar at 20°C, colonies are pink, turbid, round, and convex with shiny surfaces. In liquid media, thin turbidity and formation of pink sediment are observed.

Catalase-positive, oxidase-negative. No growth is observed in mineral medium; weak growth is seen in the presence of ethanol, but not with glucose, acetate, citrate, methanol, ethylamine, or paraffin. Good growth is observed in mineral medium plus peptone (0.5%) and yeast extract (0.1%); in these media, addition of one of glucose, acetate, citrate, ethylamine, or paraffin (at 1%) reduces growth. Growth is enhanced in peptone-yeast extract medium by the addition of 1% NaCl. Increasing the salt concentration leads to increased formation of aggregates. No acid or gas is produced from glucose, galactose, fructose, xylose, sucrose, maltose, lactose, or glycerin. Methyl red and Voges–Proskauer reactions are negative. Does not hydrolyze starch, chitin, alginate, or cellulose. Reactions towards substrates provided by the API ZYM, API 20 NE, and Biolog GP2 panels are indicated in Table 57. Peptidoglycan diamino acid, menaquinone, and polar lipids are as described for the genus. Two unknown phospholipids may occur. Major fatty acids are 14-methylpentadecanoic acid ($C_{16:0}$ iso) and 14-methylpentadecenoic acid ($C_{16:1}$ iso); smaller amounts of $C_{18:0}$, $C_{16:1}$ ω7*c*, $C_{18:1}$ ω9*c*, $C_{16:0}$, and $C_{14:0}$ iso occur. Extinction maxima of carotenoids are at 470 and 500 nm.

Source: isolated from sediment of Station Breitengrund at 20 m depth, Western Baltic Sea.

DNA G+C content (mol%): 73.9 (HPLC).

Type strain: DSM 4725, ATCC 25902.

Sequence accession no. (16S rRNA gene): AJ430193.

2. **Blastococcus jejuensis** Lee 2006, 2395[VP]

je.ju.en′sis. N.L. masc. adj. *jejuensis* of or belonging to Jeju, Republic of Korea, the site from which the type strain was isolated.

Aerobic, motile, non-spore-forming, oxidase-negative, catalase-positive, Gram-stain-positive. Cells are cocci that occur in pairs or rods. Bud formation is observed for rod-shaped cells. Colonies are circular, smooth, transparent, and apricot in color. Starch and casein are hydrolyzed, but not elastin. Hypoxanthine, tyrosine, and xanthine are not decomposed. In API 20NE tests, glucose fermentation and indole production from tryptophan are not observed. Activities of arginine dihydrolase, urease, and β-galactosidase are not present. Nitrate is not reduced to nitrite. Esculin degradation and gelatin hydrolysis are not detected. Caprate, adipate, citrate, and phenylacetate are not assimilated. In API ZYM tests, results for leucine arylamidase and α-glucosidase are positive and weakly positive, respectively, whereas results for esterase lipase (C8), lipase (C14), trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are negative. The temperature range for growth is 10–37°C, with optimum growth at 30°C. Growth occurs at pH 6.1–10.1, with optimum growth at pH 7.1. Growth is observed in the presence of 0–1% NaCl, but not in 2% NaCl. The following substrates are used as sole carbon and energy sources: mannan, *N*-acetyl-β-D-mannosamine, amygdalin, cellobiose, D-fructose, D-galactose, D-galacturonic acid, gentiobiose, *myo*-inositol, melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl-D-glucoside, palatinose, L-rhamnose, sedoheptulosan, D-sorbitol, sucrose, D-tagatose, turanose, xylitol, acetic acid, γ-hydroxybutyric acid, α-ketovaleric acid, D-lactic acid methyl ester, succinic acid, L-asparagine, putrescine, 2,3-butanediol, adenosine, and D-glucose 6-phosphate. Tween 40, D-ribose, α-ketoglutaric acid, and methyl succinate are not utilized. The polar lipid profile contains phosphatidylcholine, diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylmethylethanolamine, and phosphatidylinositol. Mycolic acids are not present. The major cellular fatty acids are $C_{16:0}$ iso, $C_{17:1}$ ω8*c*, and $C_{15:0}$ iso. The predominant menaquinone is MK-9(H_4). Whole-cell hydrolyzates contain *meso*-DAP as the diagnostic diamino acid and arabinose and galactose as diagnostic sugars.

Source: isolated from sand sediment from Gwakji beach on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 72.3 (method not reported).

Type strain: KST3-10, NRRL B-24440, KCCM 42251.

Sequence accession no. (16S rRNA gene): DQ200983.

3. **Blastococcus saxobsidens** Urzì, Salamone, Schumann, Rohde and Stackebrandt 2004b, 258[VP]

sax.ob′si.dens. L. neut. n. *saxum* rock; L. part. adj. *obsidens* staying, remaining, occupying; N.L. masc. part. adj. *saxobsidens* rock-occupying.

Aerobic, Gram-stain-positive. Motile and nonmotile cells (1.0–1.7 µm in diameter) are coccoid, occurring in tetrads with a tendency to remain aggregated. Sparse growth on Luedemann medium, malt agar, and yeast extract-casein hydrolysates-starch-glucose agar. No growth on potato-dextrose agar or yeast extract-glucose-glycerol agar. Grows between 20 and 37°C and at pH 5–8.6; optimum growth is at 32°C and pH 6.8. No growth in 3% NaCl, except strain BC448, which can grow at 5% NaCl. Colonies are pink–orange-pigmented, irregular, and convex with a smooth to rough surface (2–3 mm in diameter). Catalase- and oxidase-positive. Nitrate is not reduced to nitrite. Carbon sources utilized for growth are: D-glucose, D-fructose, L-arabinose, ribose, *myo*-inositol, and lactose. No acid production is observed from D-fructose, *myo*-inositol, or lactose. Casein, gelatin, and starch are not hydrolyzed. DNA, tyrosine, xanthine, and hypoxanthine are not decomposed. Tweens 20, 40, 60, and 80 are not hydrolyzed. The peptidoglycan diamino acid, major menaquinone, and polar lipids are as described for the genus. Major fatty acids are 14-methyl-pentadecanoic acid ($C_{16:0}$ iso), *cis*-9-heptadecenoic acid ($C_{17:1}$ ω8*c*), and 13-methyl-tetradecanoic acid ($C_{15:0}$ iso), with smaller amounts of $C_{16:0}$, $C_{17:0}$ ante, $C_{16:1}$ iso, $C_{18:1}$ ω9*c*, and $C_{16:1}$ ω7*c*.

Source: the isolation site of the type strain was limestone sampled in Malta. Other strains were isolated from calcarenite and marble from Italy and Greece.

DNA G+C content (mol%): not reported.

Type strain: BC444, DSM 44509, NRRL B-24246.

Sequence accession no. (16S rRNA gene): AJ296061.

Genus III. **Modestobacter** Mevs, Stackebrandt, Schumann, Gallikowski and Hirsch 2000, 344[VP] emend. Reddy, Potrafka and Garcia-Pichel 2007, 2018

Philippe Normand and David R. Benson

Mo.des.to.bac′ter. L. adj. *modestus* modest, humble; N.L. masc. n. *bacter* a rod or staff; N.L. masc. n. *Modestobacter* a rod with modest growth requirements.

Gram-positive, non-spore-forming. Short rods or cocci with a tendency to remain aggregated and form short, **multiseptate filaments**. These produce slender **buds** (Figure 118). Aerobic heterotrophs **able to grow in oligotrophic** medium. Typically **psychrotolerant**. Major fatty acids include $C_{18:1}$, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. The major respiratory quinone is MK-9(H_4). The cell wall peptidoglycan contains *meso*-DAP as diamino acid, with alanine, glutamate and *meso*-DAP present in a 2:1:1 stoichiometry.

DNA G+C content (mol%): around 70.

Type species: **Modestobacter multiseptatus** Mevs, Stackebrandt, Schumann, Gallikowski and Hirsch 2000, 344[VP].

Further descriptive information

The genus was created in 2000 to accommodate strains isolated from Antarctic "soil". The morphology of the strains was found to be sufficiently special to warrant the creation not only

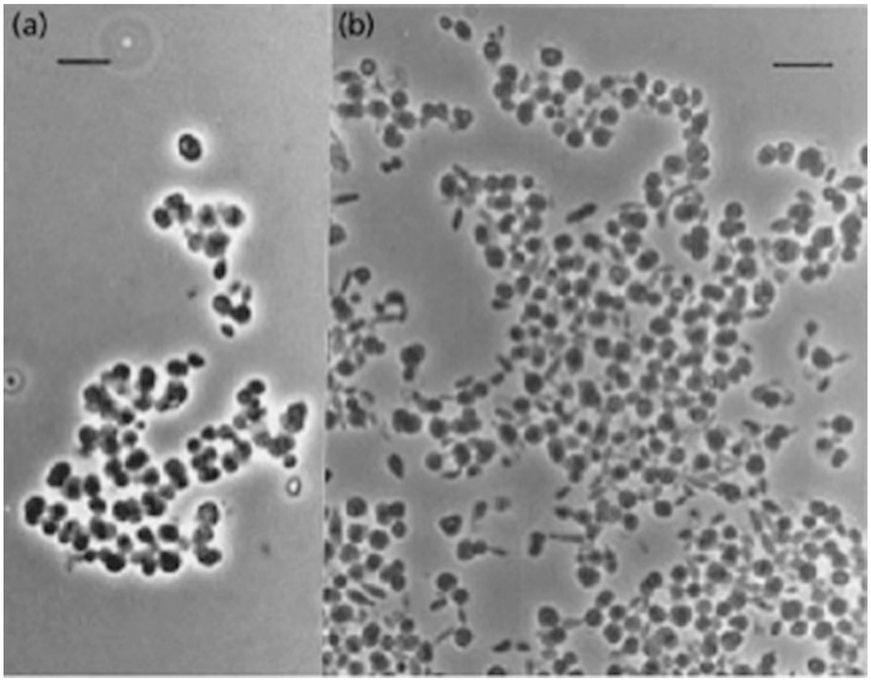

FIGURE 118. Phase-contrast light micrographs of *Modestobacter multiseptatus*. (a) Strain AA-802 grown for 4 d on PYGV agar (pH 8.0) at 16°C. (b) Strain AA-825 grown for 6 d on PYGV agar at 16°C. Bars = 5 µm. (Reprinted with permission from Mevs et al., 2000. Int. J. Syst. Evol. Microbiol. *50*: 337–346.)

[a]From Reddy et al. (2007).

of a novel species, but also of a new genus that was later positioned in the *Geodermatophilaceae* on the basis of its 16S rRNA gene sequence (Mevs et al., 2000). The word "soil" is debatable because the fine granular material found in the McMurdo dry valley being almost completely devoid of organic matter can better be called regolithic. The recent description of a second species, *Modestobacter versicolor* (Reddy et al., 2007), has permitted a more elaborate description. The two species are found in markedly different biotopes and thus have a number of distinguishing features (Table 59).

List of species of the genus *Modestobacter*

1. **Modestobacter multiseptatus** Mevs, Stackebrandt, Schumann, Gallikowski and Hirsch 2000, 344[VP] emend. Reddy, Potrafka and Garcia-Pichel 2007, 2018

mul.ti.sep.ta′tus. L. adj. *multus* much; L. adj. *septatus* fenced; N.L. masc. adj. *multiseptatus* much fenced, with many septa.

Colonies are irregularly shaped, shiny, and beige to pinkish. Cells are Gram-stain-positive, short rods or cocci with a tendency to remain aggregated. Cells show cross and longitudinal wall growth and multiply by budding and swarmer formation. Cell sizes vary (1.0–2.8 × 1.0–3.0 µm), with a mean size of 1.7 × 1.6–1.9 µm. Slender buds may become motile. Aerobic heterotroph; can grow on oligotrophic medium PYGV (Staley, 1968) or on DSMZ medium 65. Growth occurs between 0 and 28°C. Can tolerate pH 3–12, with optimum growth at pH 7.5–8.5. Positive for catalase, cytochrome oxidase, phosphatase, and amylase. Shows type II restriction endonuclease activity. H_2S is not formed from cystine or sulfate. Does not utilize fructose, xylose, or trehalose, but can utilize D-glucose, D-galactose, lactose, sucrose, mannitol, succinate, and malate. Utilization of maltose, mannose, melibiose, fucose, ribose, rhamnose, sorbitol, and *N*-acetylglucosamine is variable. Adenine, hypoxanthine, xanthine, hippurate, cellulose, chitin, dextrin, xylan, arbutin, and casein are not hydrolyzed. Utilizes peptone or yeast extract as nitrogen source and reduces nitrate aerobically or anaerobically. The main respiratory quinone is MK-9(H_4); MK-8(H_4) and MK-9(H_6) are present in small amounts. Main fatty acids are $C_{18:1}$ and $C_{16:0}$ iso. *meso*-DAP is present. Cell wall sugars are composed of galactose, glucose, and ribose.

Source: isolated from Antarctic surface "soil" from Linnaeus Terrace (1600 m) of the Asgard Range in the Transantarctic Mountains.

DNA G+C content (mol%): 68–70 (melting spectrometry; Mandel and Marmur, 1968).

Type strain: AA-826, DSM 44406, CIP 106529, JCM 12207.

Sequence accession no. (16S rRNA gene): Y18646.

2. **Modestobacter versicolor** Reddy, Potrafka and Garcia-Pichel 2007, 2018[VP]

ver.si′co.lor. L. masc. adj. *versicolor* that changes its color, of changeable color, of various colors, particolored.

Colonies are dark brown on oligotrophic medium and pink to white on copiotrophic medium, 1–4 mm in diameter, convex, entire, smooth to rugose, and slightly mucoid. Cells are short, small rods (straight, lightly curved, irregular, or even tapering), often developing into multiseptate cells, occurring singly or in pairs, sometimes remaining aggregated, and only rarely forming filaments longer than several cells. Single rods are 0.5–1.0 × 1.0–3.0 µm. Short filaments are up to 7.0 µm long. Septation is transverse (orthogonal to the long cellular axis) and apical cells may resemble buds. Motility is variable, by means of polar flagellation. Growth is observed at 4–30°C (but not at 37°C) and pH 5–9, with optimum growth at 25°C and pH 7. Produces copious melanins under oligotrophic conditions. Tolerates NaCl at concentrations less than 3%. Cells are positive for catalase, β-galactosidase, phosphatase, urease, and lipase, but negative for oxidase, gelatinase, arginine decarboxylase, lysine decarboxylase, ornithine decarboxylase, and phenylalanine deaminase. Negative for methyl red, Voges–Proskauer, and indole tests. Hydrolyzes casein and esculin, but not cellulose or starch. Reduces nitrate to nitrite. Does not produce H_2S gas and cannot grow on DNase or Simmons' citrate test plates. Utilizes a wide variety of sugars, low-molecular-mass organic acids, amino acids, and all four nitrogenous bases. Described as a nitrogen fixer, although this is debatable given that the evidence is based only on growth on nitrogen-free medium. The major fatty acids are $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{15:0}$ anteiso, and $C_{18:1}$; MK-9(H_4) is the major respiratory quinone. Its peptidoglycan contains *meso*-DAP. Other features are given in Table 59.

Source: the type strain was isolated from a biological soil crust on the Colorado Plateau, USA (Reddy et al., 2007).

DNA G+C content (mol%): 73±2.5 (spectrophotometry; DeLey et al., 1970).

Type strain: CP153-2, ATCC BAA-1040, DSM 16678.

Sequence accession no. (16S rRNA gene): AJ871304.

Family V. **Nakamurellaceae** Tao, Yue, Chen and Chen 2004, 999[VP]

Wen-Feng Chen and Tian-Shen Tao

Na.ka.mu.rel.la.ce′a.e. N.L. fem. n. *Nakamurella* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Nakamurellaceae* the *Nakamurella* family.

Yoshimi et al. (1996) proposed the bacterial genus *Microsphaera*. However, the genus name was the same as that of the fungal genus *Microsphaera* (Wallr.) Léveillé 1851, which is still used in the taxonomy of fungi and contains species that are common plant fungal pathogens that cause powdery mildew. According to Principle 2, Rule 51b(4) of the Bacteriological Code (Lapage et al., 1992), the name of the bacterial genus *Microsphaera* (Yoshimi et al., 1996) is illegitimate. Therefore, a new genus name, *Nakamurella*, was proposed for the bacterial genus. The type species *Microsphaera multipartita* Yoshimi et al. (1996) became *Nakamurella multipartita* gen. nov., comb. nov. Due to the illegitimacy of the genus name, the family *Microsphaeraceae* proposed by Stackebrandt et al. (1997) is also illegitimate and has been replaced by the new bacterial family name *Nakamurellaceae*.

The family *Nakamurellaceae* currently contains two genera, *Nakamurella* and *Humicoccus*. The family description is as given for the family *Microsphaeraceae* as proposed by Stackebrandt et al. (1997).

Type genus: **Nakamurella** Tao, Yue, Chen and Chen 2004, 999[VP].

Genus I. **Nakamurella** Tao, Yue, Chen and Chen 2004, 999[VP]

Wen-Feng Chen and Tian-Shen Tao

Na.ka.mu.rel′la. N.L. fem. dim. n. *Nakamurella* to honor the Japanese microbiologist Kazunori Nakamura.

Spherical cells, 0.8–3.0 µm; occur singly or sometimes in clusters. A cell wall structure is observed in the middle of each cell in early exponential growth phase and a number of septa are found in late exponential phase. Nonmotile. No spores are formed. Gram-stain-positive. Chemoorganotrophic and strictly aerobic metabolism with oxygen as the terminal electron acceptor. **Growth rate is low.** Visible colonies appear on agar media after 10 d of incubation. Catalase-positive. Oxidase-negative. Contains *meso*-DAP in cell wall peptidoglycan. **MK-8(H_4) is the major quinone.** Major fatty acids are $C_{16:0}$ iso, $C_{15:0}$ iso, and $C_{18:1}$.

DNA G+C content (mol%): 67.5 (HPLC).

Type species: **Nakamurella multipartita** Tao, Yue, Chen and Chen 2004, 999[VP].

Further descriptive information

Respiratory quinone profiles of activated sludge can provide valuable information on the bacterial population structure of the sludge. Analysis of an activated sludge loaded with sugar wastewater revealed that menaquinones accounted for more than half of the total quinone content of the sludge and that MK-8(H_4) was the predominant menaquinone (Yoshimi et al., 1996). Also, microscopic studies showed that the sludge contained large numbers of well-compacted flocs consisting of large coccus-shaped bacteria. The single species of the genus *Nakamurella*, *Nakamurella multipartita* (previously known as *Microsphaera multipartita*), a coccus-shaped bacterium, is one of the bacteria that predominated in the sludge studied. It produces menaquinones, with MK-8(H_4) as the major component.

Cells of *Nakamurella multipartita* are Gram-stain-positive, nonmotile, non-spore-forming, and coccus-shaped. Cells are 0.8–3.0 µm in diameter and occur singly, in pairs, or in small irregular clusters (Figure 119). Rod-shaped or filamentous cells have not been observed at any stage of growth. The cell size depends on the growth stage; large cells (more than 2.0 µm in diameter) predominate in the early stages of the exponential growth phase and the proportion of small cells increases during the late stages of the exponential growth phase (Figure 120). Thin-section electron microscopy revealed that a cell wall-like structure occurred in the middle of each cell at the early growth phase (Figure 121). Many septa were observed in the cells during the late exponential growth phase (Figure 121).

Growth rate is low under all growth conditions tested, even under optimal growth conditions. Doubling time is about 11 h in a liquid medium at pH 7.0 and 25°C. Visible colonies appear on agar media after 10 d of incubation. Colonies are circular, smooth, convex, and white at the early stage of growth. After about 2 weeks of incubation, the colonies become cream colored.

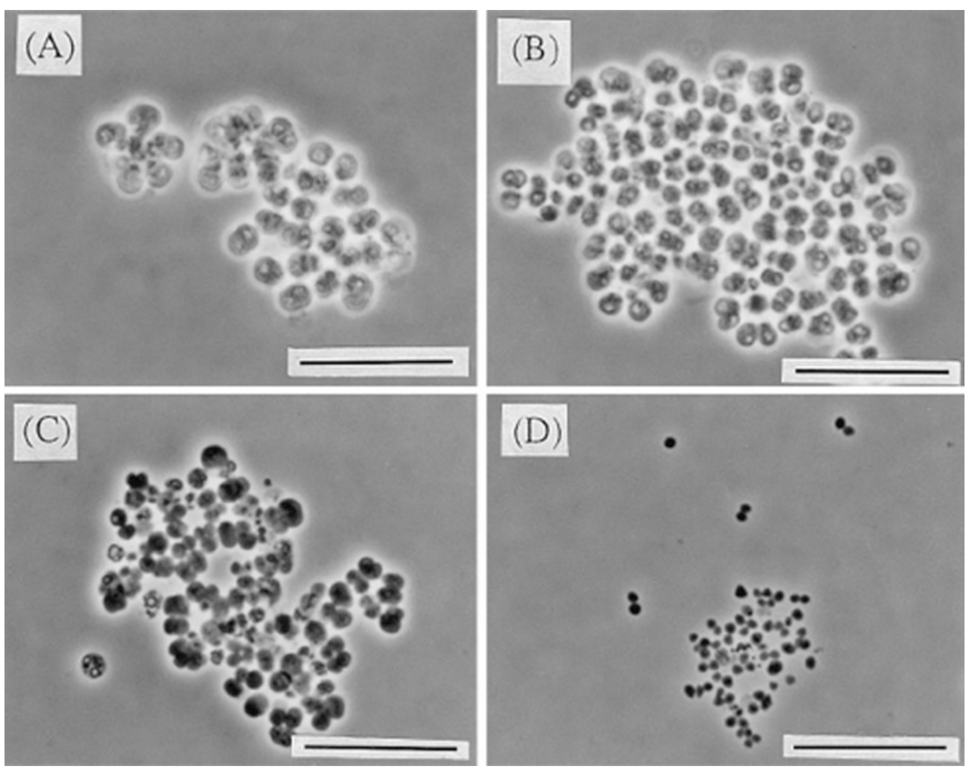

FIGURE 119. Phase-contrast photomicrographs of cells of *Nakamurella multipartita*. Cells were harvested in the early growth phase (A), in the mid-exponential phase (B), in the late exponential phase (C), and in the stationary phase (D). Bars = 10 µm. (Reprinted with permission from K. Nakamura.)

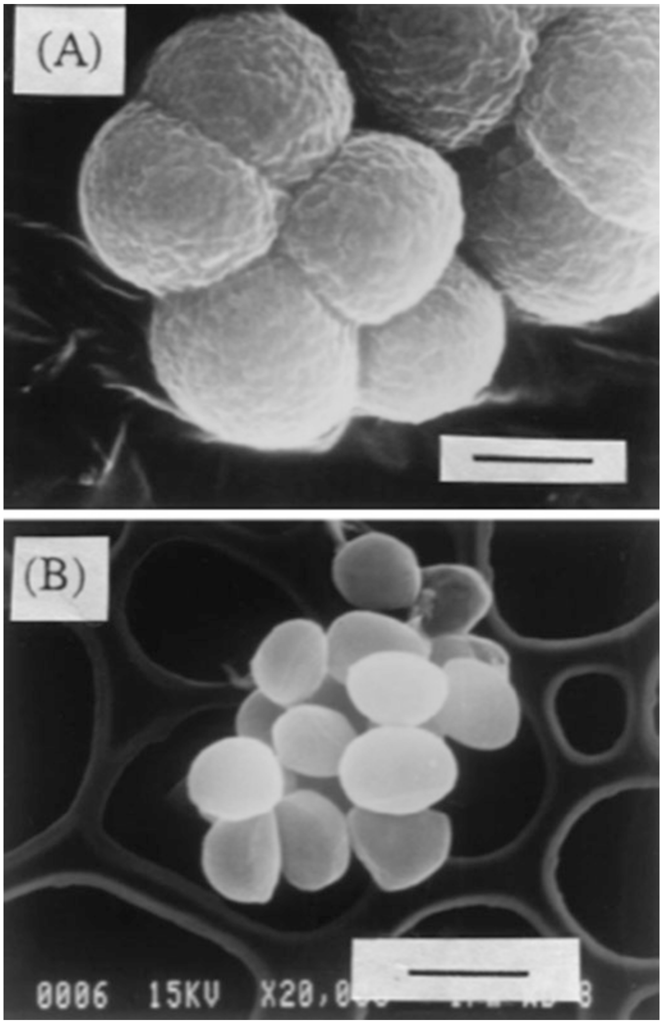

FIGURE 120. Scanning electron micrographs of cells of *Nakamurella multipartita*. Cells were harvested in the exponential phase (A) and in the stationary phase (B). Bars = 1 µm. (Reprinted with permission from K. Nakamura.)

Cells are able to uptake all sugars supplied, and large amounts of polysaccharide accumulate in cells in the absence of nitrogen and phosphate sources. A culture containing 1 g/l of the type strain (Y-104^T) of *Nakamurella multipartita* takes up 1 g/l glucose almost completely in 1 h. The polysaccharide content of the cells is about 50% (w/w, dry cells) after 1 h of incubation.

Obligately aerobic chemoorganotroph with oxygen as the terminal electron acceptor. It is unable to grow under strictly anaerobic conditions. Optimum growth conditions are 25°C and pH 7.0. Grows at NaCl concentrations of <6%.

Catalase is produced. Oxidase activity is negative. Alcohols and sugars including glucose, fructose, mannose, galactose, xylose, sucrose, maltose, lactose, mannitol, sorbitol, ethanol, propanol, glycerol, and starch are good carbon sources. Pyruvate, alanine, glutamate, glutamine, and histidine are also utilized. Acetate, malate, succinate, arginine, asparagine, methanol, and glycogen are not utilized.

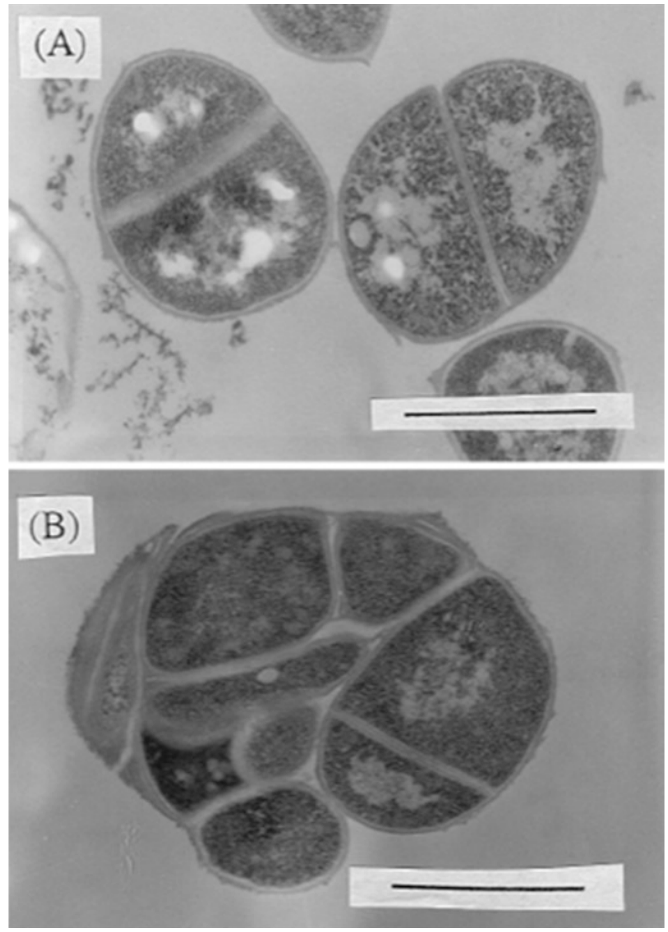

FIGURE 121. Transmission electron micrographs of thin sections of cells of *Nakamurella multipartita*. Cells were harvested in the early growth phase (A) and in the late exponential phase (B). Bars = 1 µm. (Reprinted with permission from K. Nakamura.)

The major quinone component is a menaquinone with eight tetrahydrogenated isoprene units [MK-8(H$_4$); 97.0%]. MK-7(H$_4$), MK-8(H$_2$), and MK-9(H$_4$) are minor components. Major fatty acids are $C_{16:0}$ iso (19.7%), $C_{15:0}$ iso (15.7%), and $C_{18:1}$ (14.0%); smaller, but substantial amounts of fatty acids are $C_{16:0}$ (10.3%), $C_{15:0}$ anteiso (9.2%), $C_{17:0}$ iso (8.5%), and $C_{17:0}$ anteiso (5.2%).

The cell wall peptidoglycan contains *meso*-DAP. Mycolic acids are not present.

Enrichment and isolation procedures

The only isolate of the only species described thus far was obtained from activated sludge acclimated with sugar-containing synthetic wastewater.

Activated sludge was cultured aerobically in a fed-batch reactor system (length of cycle, 8 h) with synthetic wastewater containing (per liter) 0.75 g glucose, 0.03 g peptone, 0.03 g yeast

extract, 0.1 g $(NH_4)_2SO_4$, and 0.07 g KH_2PO_4. At the end of each batch cycle, the sludge was sedimented, and two-thirds of the supernatant was replaced with the same volume of the synthetic medium. After 90 d of acclimation, bacteria were isolated from the sludge by the dilution plate method with GPY agar, which contained (per liter) 1.0 g glucose, 0.5 g peptone, 0.5 g yeast extract, 0.1 g KH_2PO_4, 0.1 g $(NH_4)_2SO_4$, and 0.1 g $MgSO_4 \cdot 7H_2O$ (pH 7.0). The plates were incubated at 25°C for 20 d. Colonies appearing on the plates were picked for standard purification.

Maintenance procedures

Nakamurella multipartita can be maintained on GPY agar slants and subcultured every month. For routine phenotypic tests, cells were grown aerobically at 25°C in GPY medium. The organism also can be maintained by lyophilization.

Acknowledgements

The authors would like to thank Professor Kazunori Nakamura for reading the manuscript of this chapter.

List of species of the genus *Nakamurella*

1. **Nakamurella multipartita** Tao, Yue, Chen and Chen 2004, 999[VP]

mul.ti.par.ti'ta. L. adj. *multus* much, great, many; L. fem. part. adj. *partita* (from L. v. *partio partire* to divide, part, distribute) divided, parted, distributed; N.L. fem. part. adj. *multipartita* micro-organisms having many divisions inside the cell.

The morphology of this species and its chemotaxonomic characteristics are the same as those described above for the genus. After about 2 weeks of incubation the colonies are cream colored. The optimum growth temperature is 25°C. The optimum pH is 7.0. No growth occurs at NaCl concentrations of 7% or more. The doubling time is about 11 h in liquid medium. The polysaccharide content of the cells may be high [sometimes more than 50% (w/w) depending on the culture conditions]. Catalase-positive. Oxidase-negative. Good carbon sources are sugars and alcohols and include D-xylose, D-lactose, mannitol, sorbitol, glycerol, ethanol, and propanol. Starch, pyruvate, alanine, glutamate, glutamine, and histidine are also utilized. Glycogen, methanol, acetate, malate, succinate, arginine, and asparagine are not utilized.

Source: occurs in activated sludge cultured in fed-batch reactors under aerobic conditions.

DNA G+C content (mol%): 67.5 (HPLC).

Type strain: ATCC 700099, JCM 9543, DSM 44233, CCM 4621, K. Nakamura Y-104.

Sequence accession no. (16S rRNA gene): Y08541.

Note: previously known by the illegitimate name *Microsphaera multipartita* (Yoshimi et al., 1996).

Genus II. **Humicoccus** Yoon, Kang, Jung and Oh 2007, 59[VP]

Jung-Hoon Yoon

Hu.mi.coc'cus. L. n. *humus* the soil; Gr. masc. n. *kokkos* a grain or berry; N.L. masc. n. *Humicoccus* coccus isolated from soil.

Cells are cocci, 0.6–1.2 µm in diameter. Gram-stain-positive. Non-spore-forming. **Nonmotile. Strictly aerobic.** Catalase-positive. Oxidase-negative. Nitrate is not reduced. Colonies are **light yellow** in color on nutrient agar. **The cell wall peptidoglycan contains *meso*-DAP. The whole-cell sugars are galactose, mannose, xylose, and rhamnose**. The major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidyldimethylethanolamine. **The predominant menaquinones are MK-8(H_4) and MK-9(H_4).** The cellular fatty acid profile consists of straight-chain and branched fatty acids.

DNA G+C content (mol%): 72.6 (HPLC).

Type species: **Humicoccus flavidus** Yoon, Kang, Jung and Oh 2007, 59[VP].

Further descriptive information

Humicoccus flavidus is the sole species of this genus. Cells may occur singly, in pairs, or in clusters when cultivated on nutrient agar. *Humicoccus flavidus* was isolated by using 10× diluted nutrient agar. However, it grows better on full-strength nutrient agar than on 2×, 5×, or 10× diluted nutrient agar. *Humicoccus flavidus* also grows better on nutrient agar than on trypticase soy agar and marine agar 2216. Growth occurs in the absence of NaCl. Characteristics are given in detail in the species description and are shown in Table 60. Phylogenetically, members of the genus *Humicoccus* are most closely related to *Nakamurella multipartita* (previously *Microsphaera multipartita*), family *Nakamurellaceae*, suborder *Frankineae* (Yoshimi et al., 1996; Stackebrandt et al., 1997; Tao et al., 2004), which has been elevated to order *Frankiales* in the taxonomic roadmap to the present volume. The clustering of the genera *Humicoccus* and *Nakamurella* is shown in phylogenetic trees constructed using three tree-making algorithms, i.e. the neighbor-joining, maximum-likelihood, and maximum-parsimony algorithms. The 16S rRNA gene sequence similarity value between the type strains of *Humicoccus flavidus* and *Nakamurella multipartita* is 96.5%. The 16S rRNA gene sequence similarity values between the type strain of *Humicoccus flavidus* and those of some other related genera are as follows: *Acidothermus* (92.4%), *Blastococcus* (93.5–93.9%), *Geodermatophilus* (92.0%), *Modestobacter* (92.8–93.0%), and *Sporichthya* (93.2–93.7%).

Enrichment and isolation procedures

Humicoccus flavidus was isolated from soil from Dokdo, an island of Korea. No selective media or enrichment procedures have

[a]Symbols and abbreviations: +, positive; –, negative; Gal, galactose; Glc, glucose; Man, mannose; Xyl, xylose; Rha, rhamnose.

[b]Data taken from Yoshimi et al. (1996) and Yoon et al. (1993). Cells of the two genera are spherical and Gram-stain-positive. Both grow at 10°C and are positive for: catalase activity; hydrolysis of esculin, starch and urea; utilization of D-glucose, D-fructose, D-galactose, D-mannose, D-xylose, sucrose, and maltose; and susceptibility to streptomycin, chloramphenicol, neomycin, and oleandomycin. The two genera are negative for: motility; oxidase activity; anaerobic growth; hydrolysis of tyrosine and xanthine; utilization of acetate; and susceptibility to penicillin G, ampicillin, cephalothin, and carbenicillin.

yet been described that are specific for organisms of this genus. The genus *Humicoccus* may grow on a wide range of media. If identical samples are available, isolation of the genus *Humicoccus* may be achieved by the standard dilution-plating technique by using nutrient agar or 2–10× diluted nutrient agar.

Maintenance procedures

For short-term preservation, serial transfer from agar slants of appropriate media is recommended. Agar slants can be kept at 4°C for at least 2 months. For long-term preservation, lyophilization and storage in liquid nitrogen or in frozen glycerol suspensions are suitable. For lyophilization, the cell mass is suspended in an appropriate fluid, such as 20% (w/v) skim milk. For storage in liquid nitrogen, cell mass is inoculated into cryo-tubes containing an appropriate fluid such as 20% (w/v) glycerol. The glycerol suspension is prepared by making a suspension with cell mass in aqueous glycerol in the appropriate vial or tube. The vial or tube is stored at −20°C or −70°C.

Differentiation of the genus *Humicoccus* from other genera

Members of the genus *Humicoccus* have the same cellular morphology, peptidoglycan diamino acid type, and polar lipid profile as those of the genus *Nakamurella* (Yoon et al., 2007; Yoshimi et al., 1996). However, members of the genus *Humicoccus* can be distinguished from those of the genus *Nakamurella* by differences in the predominant menaquinone type, the fatty acid profile, and the whole-cell sugar profile (Table 60). Members of the genus *Humicoccus* contain similar amounts of MK-8(H_4) and MK-9(H_4) as the predominant menaquinones, whereas members of the genus *Nakamurella* contain only MK-8(H_4) as the predominant menaquinone. The genus *Humicoccus* contains $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{17:0}$ as the major fatty acids, whereas the genus *Nakamurella* contains $C_{16:0}$ iso and $C_{18:1}$ ω9*c* as the major fatty acids. Unsaturated and 10-methyl fatty acids, which are present in the genus *Nakamurella*, are not detected in the genus *Humicoccus*. There is a slight difference in whole-cell sugars between the genera *Humicoccus* and *Nakamurella*. The genus *Humicoccus* is clearly distinguishable from the genus *Nakamurella* based on differences in some phenotypic characteristics (listed in Table 60).

List of species of the genus *Humicoccus*

1. **Humicoccus flavidus** Yoon, Kang, Jung and Oh 2007, 59[VP]

fla′vi.dus. L. masc. adj. *flavidus* pale yellow.

Cells are cocci, 0.6–1.2 μm in diameter. Gram-stain-positive. Non-spore-forming. Nonmotile. Strictly aerobic. Colonies are circular, convex, smooth, glistening, light yellow in color, and 1.0–1.8 mm in diameter after incubation for 10 d at 25°C on nutrient agar. Growth occurs at 4 and 32°C, but not at 33°C. Optimal pH for growth is 6.0–7.0; growth occurs at pH 5.0 and 8.5, but not at pH 4.5 or 9.0. Growth occurs in 0–4% NaCl. Growth does not occur under anaerobic conditions on nutrient agar or on nutrient agar supplemented with nitrate. Nitrate is not reduced. Gelatin is hydrolyzed. Tweens 20, 40, 60, and 80 are not hydrolyzed. H_2S and indole are not produced. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase are absent. In assays with the API ZYM system, esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and β-glucosidase are present, but alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are absent. Cellobiose, trehalose, L-arabinose, and salicin are utilized as sole carbon and energy sources. Benzoate, citrate, and formate are not utilized as sole carbon and energy sources. The whole-cell sugars are galactose, mannose, xylose, and rhamnose. The major polar lipids are diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidyldimethylethanolamine. The major fatty acids (>10% of total fatty acids) are $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{17:0}$.

Source: isolated from soil.

DNA G+C content (mol%): 72.6 (HPLC).

Type strain: DS-52, KCTC 19127, CIP 108919.

Sequence accession no. (16S rRNA gene): DQ321750.

Family VI. **Sporichthyaceae** Stackebrandt, Rainey and Ward-Rainey 1997, 487[VP]

Philippe Normand and David R. Benson

Spo.rich.thy.a.ce′a.e. N.L. fem. n. *Sporichthya* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Sporichthyaceae* the *Sporichthya* family.

A group of rare microorganisms isolated from cultivated soils that have a complex and unique morphology. The group is composed of a single bacterial genus, *Sporichthya* (Lechevalier et al., 1968). The two species are *Sporichthya brevicatena*, comprising a single isolate (Tamura et al., 1999), and *Sporichthya polymorpha*, only five isolates of which have been obtained over a course of 20 years. This rarity is presumably due to a lack of resistance to major antibiotics as well as to a slow growth rate using standard soil isolation procedures.

A pattern of 16S rRNA gene sequence signatures consisting of nucleotides at positions 139:224 (U–A), 186:191 (G–C), 600:638 (C–G), 839:847 (U–A), 987:1218 (A–U), 1059:1198 (U–A), and 1308:1329 (U–A) has been proposed (Stackebrandt et al., 1997). A signature of the *Sporichthyaceae* would appear to be 5′-CTTCGGGTGGGGATCAGTGGCG-3′ at coordinates 65–86 in the sequence of *Sporichthya polymorpha* DSM 46113 (sequence accession no. X72377).

Genus I. **Sporichthya** Lechevalier, Lechevalier and Holbert 1968, 279[AL]

Philippe Normand and David R. Benson

Spor.ich′thy.a. Gr. n. *spora* seed (and in biology, a spore); Gr. n. *ikhthus* fish; N.L. fem. n. *Sporichthya* an organism with fish-like spores.

Very short, aerial mycelium composed of hyphae, 0.5–1.0 µm in diameter, that grow on the surface of solid media (Figure 122). Aerial hyphae have a **unique upright posture maintained by holdfasts**, thickened cells that anchor the erect chains onto the solid surface (Figure 123 and Figure 124). The chains may be branched (rarely). **Cells in the chain look asymmetrical with constricted separations between cells.** No substrate mycelium is formed. The aerial mycelium forms rod-shaped to coccoid spores that may develop **polar flagella** when grown in liquid media. Under nitrogen-replete conditions, spores swell to yield various forms, some of which are vaguely fish-like, hence the name initially given to the genus. Cells are Gram-stain-variable, with young cells being Gram-stain-negative and older cells gradually acquiring a Gram-stain-positive reaction. The cell wall contains a large amount of LL-DAP. Facultatively anaerobic. Mesophilic; grows between 10 and 42°C. Chemoorganotrophic. Complex carbohydrates are utilized.

DNA G+C content (mol%): 71.0 (HPLC).

Type species: **Sporichthya polymorpha** Lechevalier, Lechevalier and Holbert 1968, 279[AL].

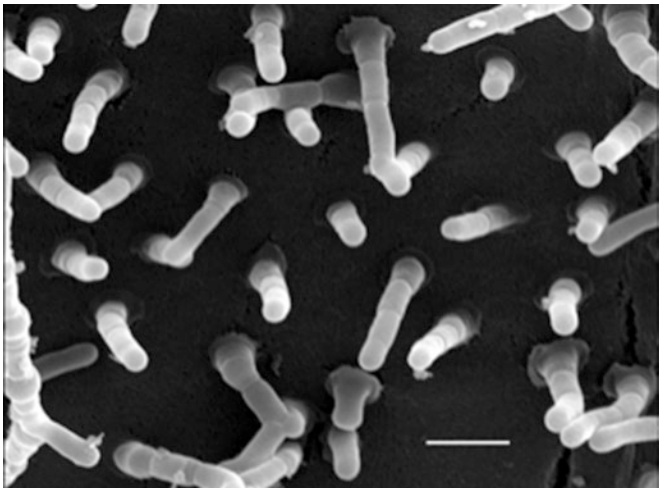

FIGURE 123. Scanning electron micrograph of *Sporichthya polymorpha* ATCC 23823[T] grown on HMG isolation medium (Suzuki, 2001) for 10 d at 27°C. Substrate mycelia are not observed. Bar = 1 μm. (Photo courtesy of Shin-ichi Suzuki, Tanabe Seiyaku Co., Saitama, Japan.)

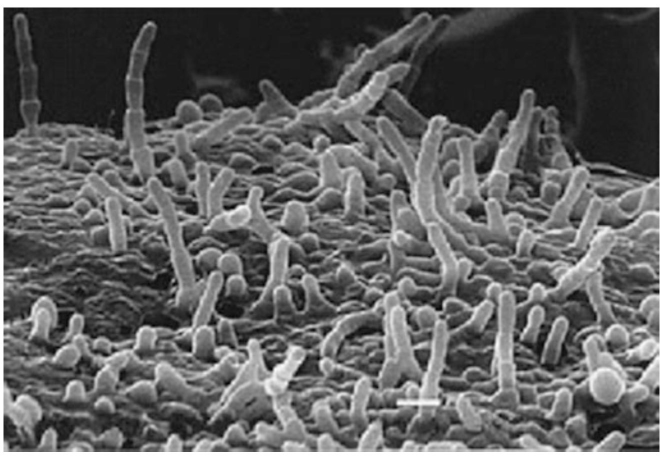

FIGURE 124. Scanning electron micrograph of *Sporichthya brevicatena* YU720-21[T] grown on yeast extract-starch agar for 4 d at 28°C. Bar = 1 μm (Tamura et al., 1999). (Reprinted with permission from Tamura et al., 1999. Int. J. Syst. Bacteriol. *49*: 1779–1784.)

TABLE 61. Differential characteristics of the two *Sporichthya* species[a]

Characteristic	*S. brevicatena*	*S. polymorpha*
Color of colony (on ISP 3 medium)	Yellowish-white	Colorless
Utilization of:		
D-Mannitol	+/−	−
L-Rhamnose	−	+
D-Xylose	+	−
Glycerol	+	−
Melibiose	+	−
Major menaquinone	MK-9(H_8)	MK-9(H_6)
Major cellular fatty acid	$C_{16:0}$ iso	$C_{16:0}$, $C_{17:1}$

[a]Data from Tamura et al. (1999).

Enrichment and isolation procedures

Isolation was obtained initially on tap water agar or on 1/10th diluted Czapek agar, but more recently Suzuki et al. (1999) used a procedure based on gellan gum and calcium chloride as growth stimulator and humic acid as sole carbon and nitrogen sources (Hayakawa and Nonomura, 1987) to assay about 30 soil samples from all continents. Many provenances yielded positive results, thus highlighting the fact there is still much progress to be made in the development of growth media for actinobacteria. All strains obtained so far have been isolated from cultivated soils. The colonies formed are, in general, very small and the help of a dissecting microscope is advised. Use of calcium chloride as a growth stimulator resulted in a marked increase in the size of colonies (Hayakawa and Nonomura, 1987).

Maintenance procedures

Transfer of slant-maintained cultures is advised every 3–4 months and storage at 4°C between transfers is recommended. Bennett or Czapek agars are used for maintenance. Long-term preservation by lyophilization from water suspension works well for most strains; use of milk is also possible, but inhibits some strains.

Differentiation of species of the genus *Sporichthya*

The genus comprises two species, *Sporichthya polymorpha* (Lechevalier et al., 1968) and *Sporichthya brevicatena* (Tamura et al., 1999), which have few discriminating features (Table 61).

List of species of the genus *Sporichthya*

1. **Sporichthya polymorpha** Lechevalier, Lechevalier and Holbert 1968, 279[AL]

po.ly.mor′pha. N.L. fem. adj. *polymorpha* (from Gr. adj. *polumorphos*, *-on*) multiform, polymorphic, microorganism having many shapes.

Aerial hyphae are chalky white, 0.5–1.2 μm in diameter, forming chains 10–25 μm in length. Division takes place by annular ingrowth of the cell wall, resulting in a sausage-string look. After division, the diameter of the growing hyphae increases, then stabilizes, and eventually decreases for a further division. Hyphae are hydrophobic. Sudan black reveals no lipid deposits. No production of pigment. Colony color ranges from chalky white on nitrogen-poor medium to slightly beige on nitrogen-rich medium.

Growth is rapid (24 h) on solid agar (Czapek, Bennett, yeast-extract-glucose agar). No growth is observed in shaken liquid culture, although without agitation, a pellicle forms on the surface of the medium and extends up the side of the container. Of the complex polymers tested, starch and esculin are hydrolyzed and some strains hydrolyze casein, but no hydrolysis of gelatin, adenine, hypoxanthine, or tyrosine is observed. No acid is produced from adonitol, arabinose, cellobiose, dextrin, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, melibiose, methyl α-D-mannoside, raffinose, rhamnose, trehalose, xylose, or methyl β-D-xyloside.

Acetate and pyruvate are utilized and lactate and succinate are used by some strains, whereas benzoate, citrate, malate, oxalate, propionate, and tartrate are not utilized. Nitrate is reduced. Phosphatase production varies. Urease-negative.

The pH range is 5–9, with optimum growth at pH 8 (Suzuki et al., 1999). The temperature range is 10–42°C, with optimum growth at 27°C.

Sporichthya polymorpha was found to be resistant to dry heating at 80°C for 1–2 h, a step recommended for its selective isolation (Suzuki et al., 1999). *Sporichthya polymorpha* strains show resistance to nalidixic acid (MIC, 5–25 μg/ml). Strains tested are susceptible to adriamycin, amikacin, bacitracin, daunorubicin, erythromycin, kanamycin, leucomycin, minocycline, nalidixic acid, novobiocin, paromomycin, rifampin, tunicamycin, and vancomycin. Use of non-sterilized 0.1% skim milk as flooding solution to recover spores was found to improve the isolation success rate.

Source: soil.

DNA G+C content (mol%): 71.0 (HPLC; Tamura et al., 1994).

Type strain: ATCC 23823, DSM 43042, IFO (now NBRC) 12702, JCM 3089, NRRL B-3709, VKM Ac-1863, KCC A-0089.

Sequence accession no. (16S rRNA gene): AB025317.

2. **Sporichthya brevicatena** Tamura, Hayakawa and Hatano 1999, 1783[VP]

bre.vi.ca.te′na. L. adj. *brevis* short; L. fem. n. *catena* chain; N.L. fem. n. *brevicatena* (nominative in apposition) a short chain, microorganism having short chains.

The name chosen by Tamura et al. (1999) implies that a feature distinguishing *Sporichthya brevicatena* from *Sporichthya polymorpha* would be the length of aerial mycelium. However, this does not appear to be striking since the photograph of *Sporichthya polymorpha* published by Lechevalier and Lechevalier (1989) shows chains of cells of 3 μm, whereas those published by Tamura et al. (1999) are even longer at 5 μm. That the two species are distinct is indeed the case given the low DNA–DNA hybridization result (30%) (Tamura et al., 1999), even though the genetic distance of 1.3% in the 16S rRNA gene sequence is not high. *Sporichthya brevicatena* comprises a single isolate, which would now be inadvisable according to Recommendation 30b of the Bacteriological Code (Lapage et al., 1992).

Source: soil.

DNA G+C content (mol%): 71.0 (HPLC; Tamura et al., 1994).

Type strain: YU720-21, IFO 16195.

Sequence accession no. (16S rRNA gene): AB006164.

Family I. **Glycomycetaceae** Rainey, Ward-Rainey and Stackebrandt 1997, 487^VP emend. Labeda and Kroppenstedt 2005, 1690

David P. Labeda

Gly.co.my.ce.ta.ce′a.e. N.L. masc. n. *Glycomyces -etis* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Glycomycetaceae* the *Glycomyces* family.

The family contains the genera *Glycomyces* and *Stackebrandtia.* Aerobic. Gram-stain-positive, non-acidfast, nonmotile actinomycetes comprising the genera *Glycomyces* and *Stackebrandtia.* Branched substrate mycelium (approximately 0.35–0.5 μm in diameter) and, on some media, aerial mycelia are produced. Mycolic acids are absent. Catalase-positive. **Contain *meso*-diaminopimelic acid as the diamino acid. Cell walls contain *N*-glycolylmuramic acid. Whole-cell sugar pattern contains ribose as a diagnostic sugar along with other genus-specific sugars. Phospholipid content includes phosphatidylglycerol and diphosphatidylglycerol in addition to other genus-specific phospholipids. The 16S rRNA gene pattern of 16S rRNA gene signature nucleotides contains 70:98 (A–U), 415 (C), 449 (C), 534 (G), 681:709 (A–U), 825:875 (G–C), 999:1041 (C–G), 1059:1198 (C–G), 1064:1192 (G–G), 1117:1183 (A–U), and 1309:1328 (C–G).**

DNA G+C content (mol%): 71–73.

Type genus: **Glycomyces** Labeda, Testa, Lechavalier and Lechevalier 1985, 419^VP emend. Labeda and Kroppenstedt 2004, 2345.

Key to the genera of the family *Glycomycetaceae*

1. The whole-cell sugar pattern consists of galactose, mannose, ribose, and xylose. Phospholipid pattern consists of significant amounts of phosphatidylinositol mannosides and phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and phosphoglycolipids of unknown composition. The menaquines predominantly contain 10, 11, and/or 12 isoprene units, but the degree of unsaturation varies within each species. Fatty acid profile contains pentadecanoic, iso-hexadecanoic, and anteiso-heptadecanoic acids as the predominant components along with a slightly less iso-pentanoic acid.

   → Genus I. **Glycomyces**

2. The whole-cell sugar pattern consists of inositol and ribose, with traces of arabinose and mannose. The phospholipid pattern consists of phosphatidylglycerol, diphosphatidylglycerol, and two additional unknown phospholipids. The predominant menaquinones are MK-10(H_4), MK-10(H_6), MK-11(H_4), and MK-11(H_6). Fatty acid profile is rich in branched chain and saturated components including 10-methyl branched heptadecanoic acid and iso-branched 2-hydroxy fatty acids.

   → Genus II. **Stackebrandtia**

Genus I. **Glycomyces** Labeda, Testa, Lechavalier and Lechevalier 1985, 419^VP emend. Labeda and Kroppenstedt 2004, 2345

David P. Labeda

Gly.co.my′ces. Gr. adj. *glukus* sweet to the taste or smell; Gr. masc. n. *mukês* a mushroom; N.L. masc. n. *Glycomyces* a sweet (glycolipid-containing) mushroom.

Vegetative mycelia are branching (diameter approximately 0.35–0.40 μm); aerial mycelium may be produced on certain growth media. Oval, spherical, or rod-like spores may be formed on the vegetative hyphae in some species; chains of square-ended conidia may be produced on aerial hyphae. Gram-stain-positive. Lysozyme-sensitive. Catalase-positive and aerobic. **Type II cell-wall composition (*meso*-diaminopimelic acid and glycine) and whole-cell sugar pattern consisting of galactose, mannose, ribose, and xylose. Phospholipid pattern consists of significant amounts of phosphatidylinositol mannosides and diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphoglycolipids of unknown composition**. The menaquinones predominantly contain 10, 11, and/or 12 isoprene units, but the degree of unsaturation varies within each species.

DNA G+C content (mol%): 71–73.

Type species: **Glycomyces harbinensis** Labeda, Testa, Lechevalier and Lechevalier 1985, 420^VP.

Further descriptive information

The genus *Glycomyces* was defined by Labeda et al. (1985) for actinomycete species that produce chains of spores on aerial sporophores, have a peptidoglycan composed of D-glycine, L-alanine, D-alanine, D-glutamic acid, *meso*-diaminopimelic acid (*meso*-A_2pm), glucoseamine, and muramic acid, and with a whole-cell sugar pattern consisting of arabinose and xylose as diagnostic sugars. These observations correspond to a type II cell wall and whole-cell sugar pattern D *sensu* Lechevalier and Lechevalier (1970). The species in this genus do not contain nitrogenous phospholipids, but phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositolmannosides are present, corresponding to a type PI phospholipid pattern *sensu* Lechevalier et al. (1977). The original genus description (Labeda et al., 1985) specified that the menaquinones generally present were those with 10 isoprene units which are tetra- to hexahydrogenated,

[b]Menaquinones listed as percentage of the total present. Quantitation is not presented for strains where menaquinone content has been determined qualitatively by mass spectroscopy.

[c]Determined by mass spectrometry.

[d]Abbreviations are exemplified by MK-9(H_4), a menaquinone which has two of the nine isoprene units hydrogenated.

but this has been recently emended (Labeda and Kroppenstedt, 2005) based on data from newly described species to include menaquinones that predominantly contain 10, 11, or 12 isoprene units with the degree of saturation being a species characteristic (see Table 62).

Enrichment and isolation procedures

Glycomyces strains can be selectively isolated from soil using the procedure described by Labeda and Kroppenstedt (2005). A 1:9 suspension of soil in sterile tap water is heated at 60°C for 5 minutes, and further dilutions are prepared in sterile tap water and spread on the surface of Czapek's sucrose agar (Waksman, 1950) supplemented with 50 μg/ml each of cycloheximide and nystatin, 10 μg/ml streptomycin, and 25 μg/ml novobiocin. After 3 weeks of incubation at 28°C, *Glycomyces*-like colonies will generally be observed growing on the surface of the plates if present in the samples. The identities of isolates can be confirmed most easily from comparison of their 16S rRNA gene sequences with those of authentic *Glycomyces* species, but observation of genus-specific chemotaxonomic characteristics, including presence of *meso*-A_2pm, arabinose and xylose as diagnostic whole-cell sugars, and lack of nitrogenous phospholipids, can also confirm their genus identity.

Recently, Gu et al. (2007) isolated a new endophytic species, *Glycomyces sambucus*, from the stem of *Sambucus adnata* Wall. The plant stems were surface-sterilized using the method of Coombs and Franco (2003) as modified by Gu et al. (2006), in which plant roots or stems are air-dried for 2 d, cut into segments, washed for 1 minute in 99% ethanol, 6 minutes in 3.125% sodium hypochlorite, 30 seconds in 99% ethanol, and finally rinsed in sterile reverse osmosis water. The stem samples were then aseptically sliced with a sterile blade and plated on BL-2 agar plates (glucose, 5 g; soluble starch, 5 g; acid hydrolysate of casein, 2 g; yeast extract 1 g; NaCl, 5 g; $CaCO_3$, 5 g; agar, 15 g; distilled water, 1 l; supplemented with 100 μg/ml penicillin), which were incubated for 2–4 weeks at 27°C. Growth of the microorganism around the stem material was observed with a stereomicroscope and subcultured onto yeast extract-malt extract agar.

Maintenance procedures

Working cultures of *Glycomyces* can be maintained as refrigerated (4°C) agar slants on appropriate media such as yeast extract-malt extract agar (Shirling and Gottlieb, 1966) or NZamine agar (DSMZ medium 554). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques. Strains have also been successfully stored for shorter periods as quick-frozen stationary-phase broth cultures or mycelial suspensions in 20% aqueous glycerol at −20° to −72°C.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium no. 554 (DSMZ, 2001) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine agar. Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using methods previously described by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Sasser (1990) and Saddler et al. (1991).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea are typically determined using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium no. 554 and salt tolerance on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Glycomyces* from other genera

The genus *Glycomyces* is distinct from other actinomycete genera on the basis of phylogeny as determined from 16S rRNA gene sequences (Figure 125), and this is doubtless the most valuable characteristic in differentiating *Glycomyces* species from

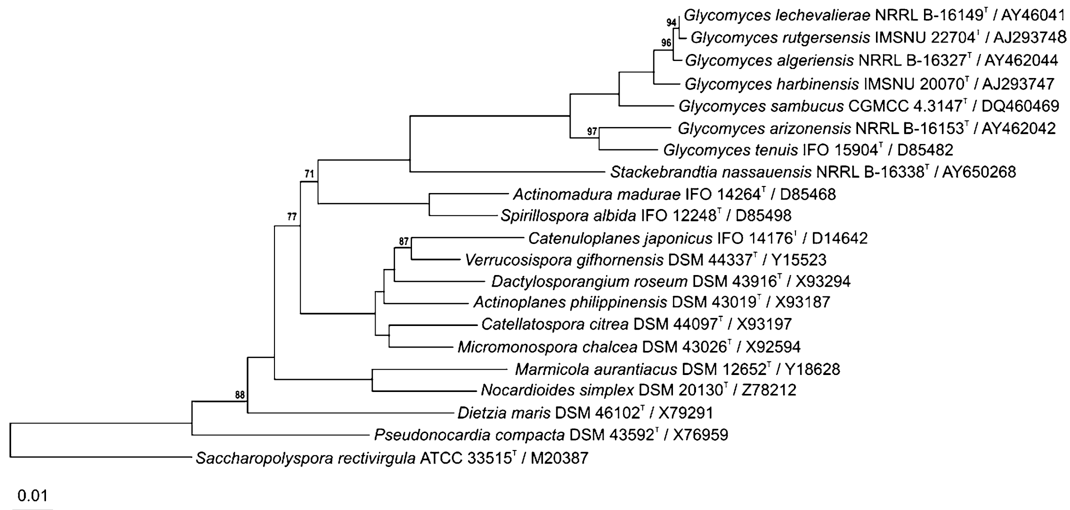

FIGURE 125. Phylogenetic tree for the genera *Glycomyces* and *Stackebrandtia* and near neighbors calculated from 16S rDNA sequences using Kimura's evolutionary distance method (1980) and the neighbor-joining method of Saitou and Nei (1987). Bar marker scale = 0.01 nucleotide substitutions per site.

TABLE 63. Comparison of chemotaxonomic profile of *Glycomyces* and *Stackebrandtia* with phylogenetically nearest taxa

Characteristic	*Glycomyces*	*Actinomadura*	*Spirillospora*	*Stackebrandtia*
A_2pm isomer	*meso*	*meso*	*meso*	*meso*

Polar lipids[a]	PIM, PI, PG, DPG, PGL_1, PGL_2	PI, PG, DPG	PI, PIM, DPG	PG, DPG, PL_1, PL_2
Predominant menaquinones	Species specific	MK-9(H_4), MK-9(H_6), MK-9(H_8)	MK-9(H_4), MK-9(H_6)	MK-10(H_4), MK-10(H_6), MK-11(H_4), MK-11(H_6)

[a]Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; $PGL_{1,2}$, unknown phosphoglycolipids; PI, phosphatidylinositol; PIM, phosphatidylinositolmannosides; $PL_{1,2}$, unknown phospholipids.

other actinobacterial genera that produce chains of spores. The chemotaxonomic profile of members of the genus is different from the nearest phylogenetic neighboring taxa, including *Stackebrandtia*, which is closest based on 16S rRNA phylogeny (Table 63). The whole-cell sugar pattern of galactose, mannose, ribose, and xylose is unique among actinobacteria as is the observation that the menaquinone content appears species-specific. It has been reported that *Glycomyces* species also contain teichoic acids (Potekhina et al., 1993) and that these profiles may also be species-specific (Potekhina et al., 1998).

Differentiation of the species of the genus *Glycomyces*

The physiological characteristics of *Glycomyces* species are summarized in Table 64 and can be used to differentiate between species. Gross colonial morphology provides some additional information for differentiation of the species based on the color of the substrate mycelium and production and color of soluble pigments, but many of the species appear quite similar when growing on agar media. Menaquinone content appears to be a species-specific feature (Table 62) and is also useful in distinguishing *Glycomyces* species. Fatty acid profiles are not grossly different among *Glycomyces* species (Table 65) but quantitative and minor component differences observed are useful in species discrimination. Potekhina et al. (1998) have reported that teichoic acid profiles permit distinction between *Glycomyces harbinensis*, *Glycomyces rutgersensis*, and *Glycomyces tenuis*, but these data are not available for more recently described species.

[b]Fatty acids are listed as percentages of total fatty acids as determined by the Microbial Identification System software (MIDI) peak naming table.

List of species of the genus *Glycomyces*

1. **Glycomyces harbinensis** Labeda, Testa, Lechevalier and Lechevalier 1985, 420[VP]

har.bin.en′sis N.L. masc. adj. *harbinensis* of or belonging to Harbin, China (the source of the soil sample from which this organism was first isolated).

Pale-yellow to yellowish-white vegetative mycelium with very sparse production of white aerial mycelia on some media (e.g. Czapek sucrose agar). Ability to produce aerial mycelia appears to be lost on repeated transfer. Short chains of square-ended conidia produced on aerial hyphae. Soluble pigments are rarely produced, but are of yellowish shades when present. A fetid odor is produced during growth on some rich growth media. Physiological properties are shown in Table 64. Temperature range for growth is 20–42°C.

Source: soil.

DNA G+C content (mol%): 71.0 (T_m).

Type strain: LL-D05139, ATCC 43155, CGMCC 4.1364, DSM 46494, IAM 14283, IMET 43812, JCM 7347, KCTC 9362, KCTC 9655, NBRC 14487, NRRL 15337, VKM Ac-1247.

Sequence accession no. (16S rRNA gene): AJ293747, D85483.

2. **Glycomyces algeriensis** Labeda and Kroppenstedt 2004, 2345[VP]

al.ge.ri.en′sis. N.L. masc. adj. *algeriensis* from Algeria, named after the place of origin of the type strain, country of Algeria.

White to yellowish-white, waxy, plicate growth on most media. Sparse white aerial hyphae are produced on some media. Soluble pigments are not produced. Menaquinones present include MK-10, MK-11, and MK-12. Physiological properties shown in Table 64. Temperature for growth is 15–37°C.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 44727, JCM 14910, NBRL 103888, NRRL B-16327.

Sequence accession no. (16S rRNA gene): AY462044.

3. **Glycomyces arizonensis** Labeda and Kroppenstedt 2004, 2345[VP]

a.ri.zo.nen′sis. N.L. masc. adj. a*rizonensis* from Arizona, named after the place of origin of the type strain, state of Arizona, USA.

White to yellowish-white, waxy, plicate growth on most media. Aerial mycelia not produced. Faint pinkish-yellowish to yellow soluble pigment produced on some media. Menaquinones present include MK-10(H_2), MK-10(H_4), MK-11(H_2), and MK-11(H_4). Physiological properties shown in Table 64. Temperature for growth is 20–37°C.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 44726, JCM 14911, NBRC 103886, NRRL B-16153.

Sequence accession no. (16S rRNA gene): AY462042.

4. **Glycomyces lechevalierae** Labeda and Kroppenstedt 2004, 2346[VP]

le.che.val.i.e′ra.e. N. L. gen. fem. n. *lechevalierae* of Lechevalier, named for Mary Lechevalier, American microbiologist who isolated this strain and contributed substantially to the field of actinomycete biology during her career at the Waksman Institute of Microbiology.

White to yellowish-white waxy vegetative growth on most media. Light grayish-yellow plicate growth on NZamine medium (DSMZ medium no. 554). Sparse white aerial mycelia produced on several media. Menaquinones present include MK-10, MK-10(H_2), MK-10(H_4), MK-11, MK-11(H_2), and MK-11(H_4). Physiological properties shown in Table 64. Temperature for growth is 15–37°C.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 44724, JCM 14912, NBRC 103885, NRRL B-16149.

Sequence accession no. (16S rRNA gene): AY462041.

5. **Glycomyces rutgersensis** Labeda, Testa, Lechevalier and Lechevalier 1985, 420[VP]

rut.ger.sen′sis. N.L. masc. adj. *rutgersensis* of or belonging to Rutgers University where the organism was first isolated.

Yellowish-white to tan vegetative mycelium, dependent upon the growth medium. Moderate to abundant white aerial mycelium is formed on many media. Yellow to brown soluble pigments produced. A fetid odor is produced during growth on several rich growth media. Physiological properties shown in Table 64. Temperature for growth is 20–37°C.

Source: soil.

DNA G+C content (mol%): 73.0 (T_m).

Type strain: LL-I-20, ATCC 43156, CGMCC 4.1363, DSM 43812, IMET 43813, IMSNU 22074, JCM 6238, KCTC 9654, NBRC 14488, NBRC 15934, NRRL B-16106, VKM Ac-1248.

Sequence accession no. (16S rRNA gene): AJ293748, D85384.

6. **Glycomyces sambucus** Gu, Zeng and Huang 2007, 1996[VP]

sam′bu.cus. N.L. gen. n. *sambucus* of the plant genus *Sambucus.*

Yellowish-white to tan substrate mycelium, depending upon the growth medium. White aerial mycelia are produced and fragment into square-ended conidia. No soluble pigments are produced. Physiological properties shown in Table 64. Temperature for growth is 20–37°C.

Source: stems of *Sambucus adnata* Wall, a traditional Chinese medicinal plant.

DNA G+C content (mol%): 70 (T_m).

Type strain: E71, CGMCC 4.3147, DSM 45047.

Sequence accession no. (16S rRNA gene): DQ460469.

7. **Glycomyces tenuis** Evtushenko, Taptykhova, Akimov, Semyonova and Kalakoutskii 1991, 155[VP]

te′nu.is. L. masc. adj. *tenuis* thin, referring to the very thin vegetative hyphae of this strain.

The vegetative hyphae are very thin (diameter, 0.15–0.40 μm), long, densely branched, and white or ometimes cream or slightly pink. Aerial mycelium is not formed. Cultures grow well on rich organic medium and, when cultured on synthetic media, yeast extract or Casamino acids (0.3%) must be added. Physiological properties shown in Table 64. Temperature for growth is 10–40°C.

Source: an associate with *Streptomyces galilaeus* INA 5888, a soil isolate.

DNA G+C content (mol%): 72.0 (T_m).

Type strain: ATCC 49849, DSM 44171, IMSNU 22075, INA n-5888, JCM 9087, KCTC 9658, NBRC 15904, NRRL B-16895, VKM Ac-1250.

Sequence accession no. (16S rRNA gene): D85482.

Genus II. **Stackebrandtia** Labeda and Kroppenstedt 2005, 1690[VP]

David P. Labeda

Stack.e.brandt′i.a. N.L. fem. n. *Stackebrandtia* named for Erko Stackebrandt, a German microbiologist who contributed significantly to the molecular systematics of prokaryotes, including actinobacteria.

Aerobic. Gram-stain-positive, nonmotile actinomycetes. **Branched substrate mycelium (approximately 0.5 µm in diameter) and, on some media, aerial mycelia are produced.** Mycolic acids are absent. Catalase-positive. Contain *meso*-diaminopimelic acid as the diamino acid. **Cell walls contain *N*-glycolylmuramic acid. The whole-cell sugar pattern consists of inositol and ribose, with traces of arabinose and mannose. The phospholipid pattern consists of diphosphatidylglycerol, phosphatidylglycerol, and two additional unknown phospholipids. The predominant menaquinones are MK-10(H_4), MK-10(H_6), MK-11(H_4), and MK-11(H_6). Fatty-acid profile is rich in branched chain and saturated components including 10-methyl branched heptadecanoic acid and iso-branched 2-hydroxy fatty acids**. Phylogenetically nearest to the genus *Glycomyces*.

DNA G+C content (mol%): 72.4.

Type species: **Stackebrandtia nassauensis** Labeda and Kroppenstedt 2005, 1690[VP].

Further descriptive information

The fragmentation of aerial or substrate mycelium into spore-like elements has not been observed although observations of long-term growth on Czapek's sucrose agar (Figure 126) has revealed regions of growth that appear close to fragmentation. This genus could represent a new family within the order *Glycomycetales*, but this cannot be well supported based on a genus and species described for a single strain.

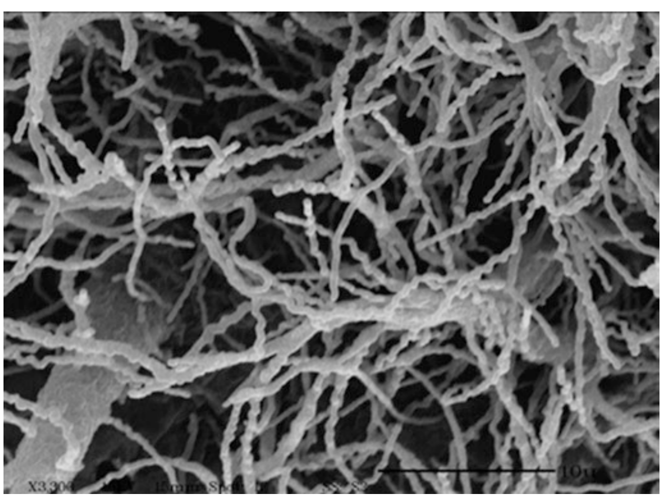

FIGURE 126. Scanning electron micrograph of 21-d growth of *Stackebrandtia nassauensis* NRRL B-16338[T] on yeast extract-malt extract (ISP-2) agar.

Maintenance procedures

Working cultures of *Stackebrandtia* can be maintained as refrigerated (4°C) agar slants on appropriate media such as yeast extract-malt extract medium (Shirling and Gottlieb, 1966) or NZamine medium (DSMZ medium 554). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration, and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium no. 554 (DSMZ, 2001) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and on NZamine medium.

Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using methods previously described by Minnikin et al. (1984), Grund and Kroppenstedt (1989), Sasser (1990), and Saddler et al. (1991).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, urea, and xanthine are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973), substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium no. 554 and salt tolerance on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Stackebrandtia* from other genera

The genus *Stackebrandtia* can be easily differentiated from *Glycomyces*, the phylogenetically nearest genus (Figure 125), based on chemotaxonomic characteristics. The whole-cell sugar pattern of *Stackebrandtia* consists of inositol and ribose with traces of arabinose and mannose, whereas *Glycomyces* typically exhibits galactose, mannose, ribose, and xylose as diagnostic sugars (Table 63). Moreover, *Stackebrandtia* and *Glycomyces* both contain diphosphatidylglycerol and phosphatidylglycerol, but *Stackebrandtia* contains two additional unknown phospholipids, whereas *Glycomyces* has significant quantities of sugar-containing phospholipids such as phosphatidylinositolmannosides and two phosphoglycolipids of unknown structure (Table 62). The fatty acid pattern of *Stackebrandtia* contains 10-methyl branched heptadecanoic acid and iso-branched 2-hydroxy fatty acids which are not found in *Glycomyces* (Table 65). The

menaquinone pattern of *Stackebrandtia*, in which MK-10(H_4), MK-10(H_6), MK-11(H_4), and MK-11(H_6) are predominant, is also different from that of the genus *Glycomyces* where the pattern appears almost species-specific but consists of menaquinones with 9, 10, 11, or 12 isoprene units with various degrees of hydrogenation (*Glycomyces* Table 64).

List of species of the genus *Stackebrandtia*

1. **Stackebrandtia nassauensis** Labeda and Kroppenstedt 2005, 1690[VP]

nas.sau.en′sis. N.L. fem. adj. *nassauensis* from Nassau, named after the place of origin of the type strain, Nassau, Providence, Bahamas.

Pale yellow to pale tan vegetative mycelium; white to yellowish-white aerial hyphae produced on most media, especially yeast extract-malt extract agar (ISP-2). Degrades or hydrolyzes allantoin, casein, esculin, gelatin, hypoxanthine, starch, and tyrosine. Neither adenine nor xanthine is degraded. Produces phosphatase. Weakly reduces nitrates. Weakly assimilates acetate and malate; does not assimilate benzoate, citrate, lactate, mucate, oxalate, propionate, succinate, or tartrate. Acid is produced from arabinose, cellobiose, dextrin, fructose, galactose, glucose, glycerol, lactose, maltose, mannose, melibiose, α-methyl-D-glucoside, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, and xylose, but not from adonitol, dulcitol, erythritol, inositol, mannitol, melezitose, or β-methyl-xyloside. Temperature range for growth is 15–37°C. Grows in the presence of 4–9% NaCl. Temperature range for growth is 15–37°C.

Source: soil.

DNA G+C content (mol%): 72.4 (HPLC).

Type strain: LLR-40K-21, CIP 108903, DSM 44728, JCM 14905, NBRC 102104, NRRL B-16338.

Sequence accession no. (16S rRNA gene): AY650268.

Order VIII. **Jiangellales** ord. nov.

Shu Kun Tang, Xiao-Yang Zhi and Wen-Jun Li

Ji.ang.el′la.les. N.L. fem. n. *Jiangella* type genus of the order; suff. -*ales* ending to denote an order; N.L. fem. pl. n. *Jiangellales* the *Jiangella* order.

The order *Jiangellales* was circumscribed for this volume mainly based on signature nucleotide patterns and phylogenetic criteria; the order contains the family *Jiangellaceae*. The order was created by elevation of suborder *Jiangellineae* of Tang et al. (2010).

Type genus: **Jiangella** Song, Li, Wang, Chen, Zhang and Xu 2005, 883[VP].

Taxonomic comments

The genus *Jiangella* was first proposed by Song et al. (2005) and assigned to the family *Nocardioidaceae* within the suborder *Propionibacterineae*, now the order *Propionibacteriales*. Upon the discovery of another novel genus, *Haloactinopolyspora* (Tang et al., 2011), phylogenetic analyses based on 16S rRNA gene sequences of the order *Propionibacteriales* revealed that the genera *Jiangella* and *Haloactinopolyspora* form a monophyletic branch at the periphery of the evolutionary radiation occupied by this order (Figure 127). It clearly shows that the genera *Jiangella* and *Haloactinopolyspora* do not belong to either the family *Nocardioidaceae* or the order *Propionibacteriales*. Further phylogenetic analyses including representatives of the entire phylum *Actinobacteria* reveal that the genera *Jiangella* and *Haloactinopolyspora* form a deep branch clearly delineated from other described orders of the class *Actinobacteria* (Figure 128). *Actinobacteria* outside these genera have 16S rRNA gene sequence similarities to the genera *Jiangella* and *Haloactinopolyspora* of less than 93.1%. Although the genera *Jiangella* and *Haloactinopolyspora* clearly belong to the class *Actinobacteria*, they do not belong to any of the described orders within that class. The 16S rRNA gene sequences of all orders of the class *Actinobacteria* (Zhi et al., 2009) and the genera *Jiangella* and *Haloactinopolyspora* were scanned for signature nucleotides. Both the genera *Jiangella* and *Haloactinopolyspora* have many unique 16S rRNA gene signature nucleotides compared with the described orders within the class *Actinobacteria*, particularly reflected in eleven different positions, namely, in 127:234 (G–C), 598:640 (C–G), 672:734 (G–C), 831:855 (U–A), 833:853 (G–C), 840:846 (A–U), 950:1231 (G–C), 952:1229 (G–C), 955:1225 (G–U), 986:1219 (U–G), and 987:1218 (C–G). Higher hierarchical taxa in the class *Actinobacteria* are mainly based on signature nucleotide patterns and phylogenetic criteria (Stackebrandt

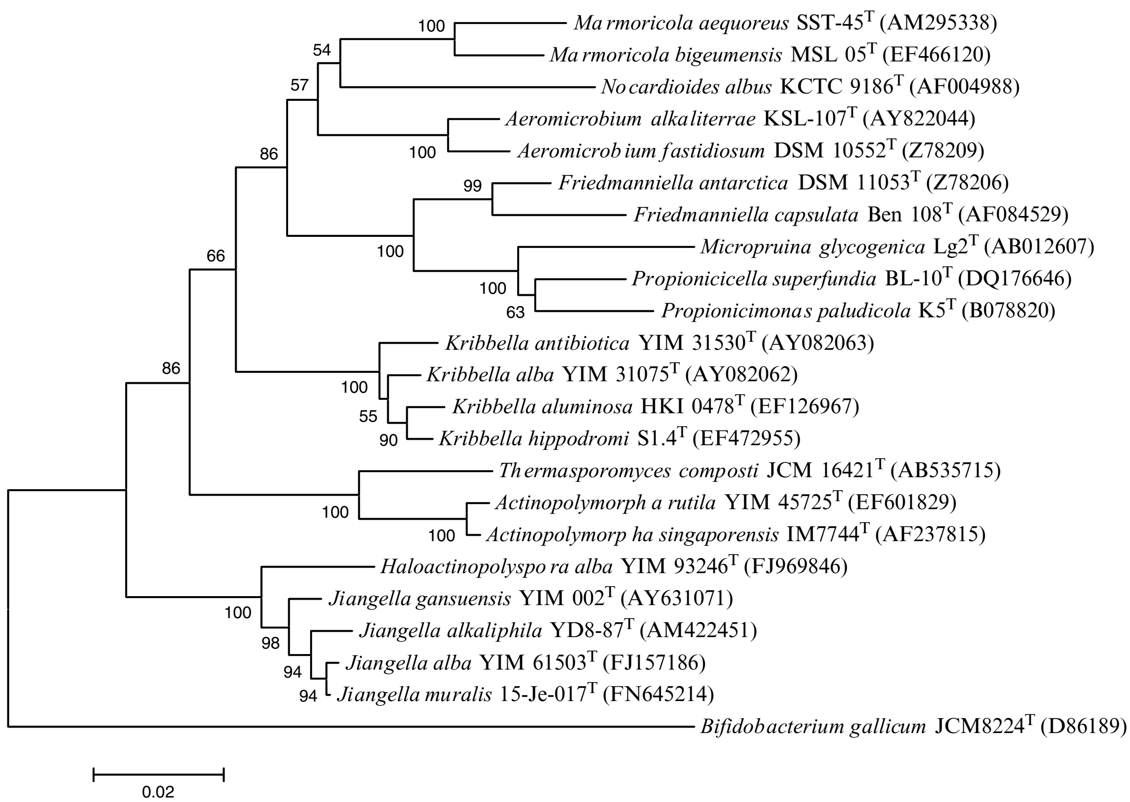

FIGURE 127. Phylogenetic dendrogram obtained by distance matrix analysis of 16S rRNA gene sequences showing the position of the genera *Jiangella* and *Haloactinopolyspora* and members of the order *Propionibacteriales*. Numbers on branch nodes are bootstrap values (1000 resamplings, only values over 50% are given). The sequence of *Bifidobacterium gallicum* JCM 8224[T] (D86189) was used as the outgroup. Bar = 0.02 substitutions per nucleotide position.

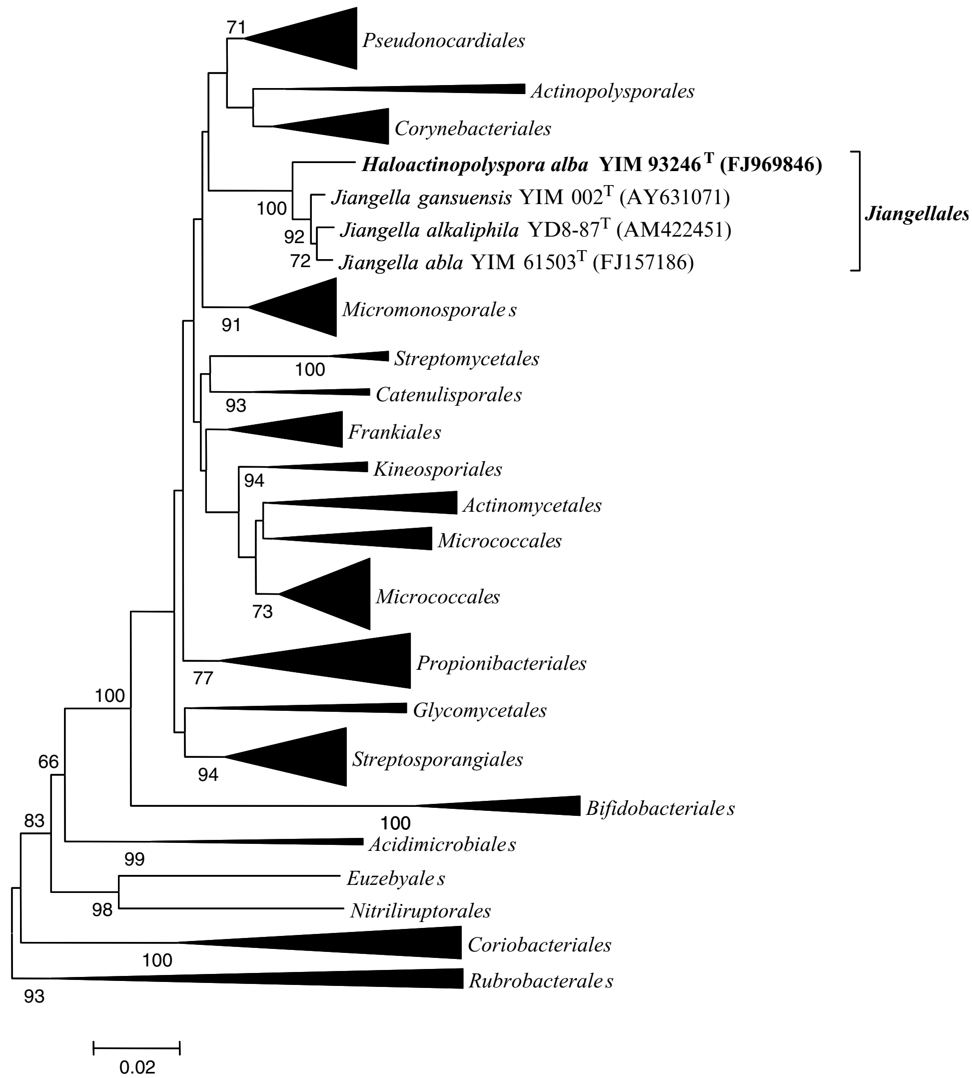

FIGURE 128. Phylogenetic position of members of the genera *Jiangella* and *Haloactinopolyspora* within the class *Actinobacteria* based on 16S rRNA gene sequence analysis. Tree topology and evolutionary distances were calculated by the neighbor-joining method (Saitou and Nei, 1987). Numbers at nodes are bootstrap percentages for the clade of each group based on 1000 replications; only values above 50% are shown. Bar = 0.02 substitutions per nucleotide position.

et al., 1997; Zhi et al., 2009). Accordingly, the genera *Jiangella* and *Haloactinopolyspora* are closely related phylogenetically and are clearly distinct from other orders in the class *Actinobacteria*. Thus, a novel suborder, *Jiangellineaes*, now the order *Jiangellales*, and a novel family *Jiangellaceae* were proposed to accommodate the genera *Jiangella* and *Haloactinopolyspora* (Tang et al., 2011).

Family I. **Jiangellaceae** Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 198[VP]

Shu-Kun Tang, Xiao-Yang Zhi and Wen-Jun Li

Ji.ang.el.la.ce′a.e. N.L. fem. n. *Jiangella* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Jiangellaceae* the family of the genus *Jiangella*.

The family *Jiangellaceae* was circumscribed for this volume mainly based on signature nucleotide patterns and phylogenetic criteria; the family contains the genera *Jiangella* and *Haloactinopolyspora*.

Members of the family *Jiangellaceae* are Gram-stain-positive, aerobic, halophilic or nonhalophilic filamentous actinomycetes.

DNA G+C content (mol%): 70–72.

Type genus: **Jiangella** Song, Li, Wang, Chen, Zhang and Xu 2005, 883[VP].

Taxonomic comments

Please refer to the order description, above.

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene sequence places the family within the order *Jiangellales*. MK-9(H_4) is the predominant menaquinone, and LL-2,6-diamionpimelate is the cell-wall diamino acid. The major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. The pattern of 16S rRNA signature nucleotides is shown in 127:234 (G–C), 598:640 (C–G), 672:734 (G–C), 831:855 (U–A), 833:853 (G–C), 840:846 (A–U), 950:1231 (G–C), 952:1229 (G–C), 955:1225 (G–U), 986:1219 (U–G) and 987:1218 (C–G).

Genus I. **Jiangella** Song, Li, Wang, Chen, Zhang and Xu 2005, 883[VP]

Xiao-Yang Zhi, Shu-Kun Tang and Wen-Jun Li

Ji.ang.el′la. N.L. fem. dim. n. *Jiangella* named after the Chinese microbiologist Cheng-Lin Jiang in recognition of his work on actinomycete taxonomy.

Gram-stain-positive, filamentous actinomycete. Aerobic, with a strictly respiratory type of metabolism. Catalase positive.

DNA G+C content (mol%): 70–71.5.

Type species: **Jiangella gansuensis** Song, Li, Wang, Chen, Zhang and Xu 2005, 883[VP].

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene sequence places the genus within the family *Jiangellaceae* and order *Jiangellales*. Its closest relative is the genus *Haloactinopolyspora*. Substrate mycelium fragments into short or elongated rods in the early stages of growth. Aerial mycelium differentiates well and no spores are formed (Figure 129). Cell wall contains LL-2,6-diaminopimelate as the diamino acid in the peptidoglycan. MK-9(H_4) is the predominant menaquinone. Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso. Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylcholine, an unknown phospholipid, and an unknown phosphoglycolipid.

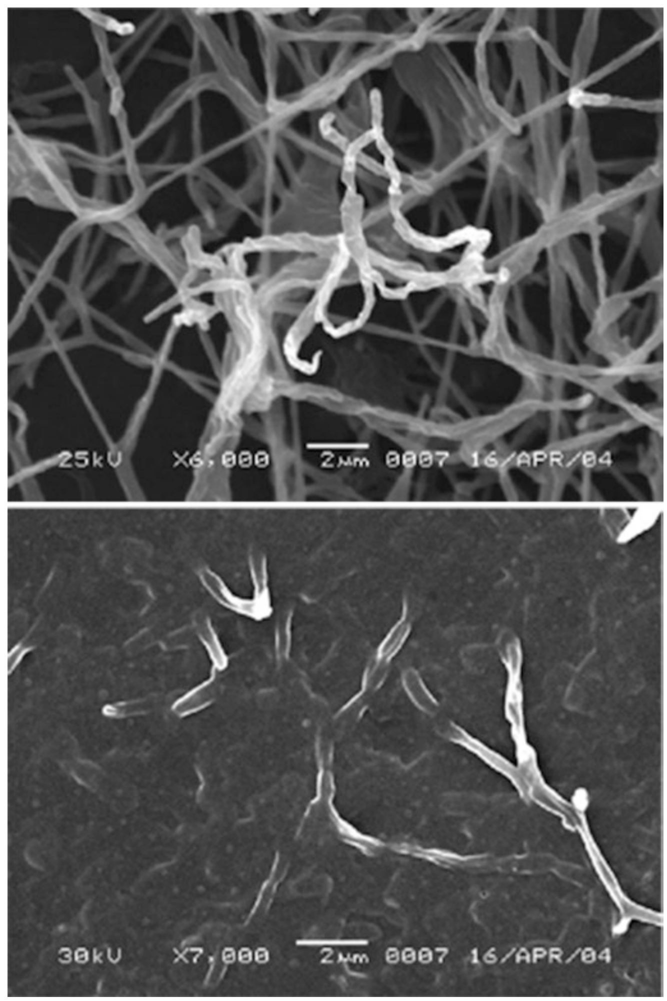

FIGURE 129. Scanning electron microscopy of *Jiangella gansuensis* grown on ISP medium 2 for 14 d at 28°C showing aerial mycelium (top) and substrate mycelium (bottom).

Enrichment and isolation procedures

The type species in the genus, *Jiangella gansuensis* YIM 002[T], was isolated from a desert soil sample collected from Sunan county, Gansu Province, northwest China, by using the dilution plating method. The medium used for selective isolation was glycerol-asparagine agar (ISP medium 5), which was incubated at 28°C for about 2 weeks. Strain *Jiangella alba* YIM 61503[T] was isolated from surface-sterilized stems of *Maytenus austroyunnanensis* collected from a tropical rainforest of Xishuangbanna, Yunnan Province, south-west China. Stem samples were air-dried at room temperature after being thoroughly washed under tap water and then surface sterilized according to the five-step sterilization procedure. Samples were then pulverized in a ceramic mortar and processed with a calcium carbonate enrichment method. The samples were serially diluted in sterile distilled water and spread-plated on glycerol-asparagine agar (ISP medium 5). Strain YIM 61503[T] was isolated after incubation at 28°C for 21 d.

[b]Strains: *Jiangella gansuensis* (Song et al., 2005; Kroppenstedt, unpublished data); *Jiangella alba* (Qin et al., 2009); *Jiangella alkaliphila* (Lee, 2008); *Jiangella muralis* (Kämpfer et al., 2011); *Haloactinopolyspora alba* YIM 93246^T (Tang et al., 2011).

Jiangella alkaliphila D8-87^T was isolated from soil in a natural cave in Jeju, Republic of Korea, by using a dilution-plating method on starch-casein agar (SCA) which was incubated at 30°C for 14 d. *Jiangella muralis* 15-Je-017^T was isolated in Jena, Germany, from the cellar wall of a house colonized with mold.

Maintenance procedures

The type strain is maintained on yeast extract-malt extract agar (ISP medium 2) and as mycelial fragments or spores in 20% (v/v) glycerol at −80°C. Lyophilized cultures are also used. *Jiangella alba* YIM 61503^T is maintained as mycelial fragments in a 20% (v/v) glycerol suspension at −80°C. *Jiangella alkaliphila* D8-87^T is maintained as mycelial fragments or spores in 20% (v/v) glycerol. *Jiangella muralis* 15-Je-017^T is maintained on organic medium M79 and preserved at −80°C.

Differentiation of the genus *Jiangella* from other genera

The characteristics differentiating *Jiangella* from the genus *Haloactinopolyspora* are shown in Table 66. *Jiangella* is a non-halophilic actinomycete, and this characteristic distinguishes it from *Haloactinopolyspora*. In addition, differences in the whole cell sugars, interpeptide bridge of peptidoglycan, polar lipids, and the major fatty acids further distinguish *Jiangella* from *Haloactinopolyspora*.

List of species of the genus *Jiangella*

1. **Jiangella gansuensis** Song, Li, Wang, Chen, Zhang and Xu 2005, 883[VP]

gan.su.en′sis. N.L. fem. adj. *gansuensis* pertaining to Gansu, a province of northwest China where the type strain was isolated.

The characteristics are as described for the genus. Optimal temperature and pH for growth are 28°C and 7.0–8.0, respectively. Utilizes arabinose, cellobiose, dextrin, fructose, galactose, glycerol glucose, inositol, lactose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, sucrose, xylitol, and

xylose as sole carbon sources, but not ribose. Positive for gelatin hydrolysis, urease, milk coagulation, and peptonization, but negative for cellulose hydrolysis, production of H_2S, starch hydrolysis, and nitrate reduction. Fatty acids present are $C_{15:0}$ anteiso (35.92%), $C_{17:0}$ anteiso (15.84%), $C_{15:0}$ iso (10.40%), $C_{17:1}$ ω8*c* (9.37%), $C_{16:0}$ iso (7.07%), $C_{17:0}$ (3.39%), $C_{17:0}$ iso (3.09%), $C_{16:1}$ iso G (2.90%), $C_{17:1}$ anteiso A (2.86%), $C_{15:0}$ 2-OH (2.28%), $C_{14:0}$ iso 2-OH (2.23%), $C_{15:1}$ anteiso A (1.31%), $C_{18:1}$ ω9*c* (1.24%), $C_{17:1}$ iso ω9*c* (1.05%), and $C_{15:0}$ (1.05%).

DNA G+C content (mol%): 70 (T_m).

Type strain: YIM 002, CCTCC AA 204001, DSM 44835, JCM 13367, KCTC 19044.

Sequence accession no. (16S rRNA gene): AY631071.

2. **Jiangella alba** Qin, Zhao, Li, Zhu, Xu and Li 2009, 2164[VP]

al′ba. L. fem. adj. *alba* white, referring to the white aerial hyphae.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast actinomycete. Grows at 15–45 °C (optimum 28°C) and pH 6.5–9.0 (optimum pH 7.0). Grows in the presence of 10% NaCl. Forms well-developed white aerial mycelia and yellowish-white to orange–yellow substrate mycelia that fragment into short or elongated rods. No diffusible pigment is produced on any of the media tested. Adenine, casein, hypoxanthine, and xanthine are degraded, but chitin, starch, DL-tyrosine, and urea are not. Positive for catalase production, gelatin liquefaction, and nitrate reduction, but negative for milk coagulation and peptonization, cellulose hydrolysis, and H_2S production. Positive for utilization of DL-arabinose, *meso*-erythritol, D-fructose, D-glucose, glycerol, inulin, maltose, D-mannitol, D-mannose, melezitose, raffinose, L-rhamnose, D-ribose, salicin, sucrose, trehalose, and D-xylose as sole carbon and energy sources. Negative for utilization of acetate, adonitol, cellobiose, citrate, D-dulcitol, formate, D-galactose, myoinositol, lactose, malate, methyl α-D-mannoside, D-sorbitol, L-sorbose, and D-xylitol. The cell wall contains LL-DAP. The whole-cell sugars are glucose, ribose, and galactose. The predominant menaquinone is MK-9(H_4). Major fatty acids (>5%) are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{14:0}$ iso, $C_{17:1}$ω8c, $C_{17:0}$ anteiso, and $C_{15:0}$ iso.

DNA G+C content (mol%): 71.9 (HPLC).

Type strain: YIM 61503, CCTCC AA 208023, DSM 45237.

Sequence accession no. (16S rRNA gene): FJ157186.

3. **Jiangella alkaliphila** Lee 2008, 1178[VP]

al.ka.li.phi′la. Arabic article *al* the; Arabic n. *qaliy* ashes of saltwort; N.L. n. *alkali* alkali; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*), friend, loving; N.L. fem. adj. *alkaliphila* loving alkaline conditions.

Aerobic, Gram-stain-positive, non-acid-alcohol-fast. Catalase positive. Forms well-developed, aerial and vegetative mycelia that fragment into short or elongated rods. The aerial mycelium is white or grayish-yellow brown. Mesophilic. The temperature for growth is in the range of 20–37°C, with good growth at 30°C. The initial pH range for growth is 6.1–10.1, with good growth at pH 8.1–10.1. Growth occurs in the presence of up to 3% NaCl. Utilizes D-arabinose, L-arabinose, D-cellobiose, dextran, D-fructose, D-glucose, inulin, D-lactose, maltose, D-mannose, L-rhamnose, D-xylose, adonitol (weak), glycerol, and D-mannitol as sole carbon sources, but not D-galactose, D-melezitose, melibiose, α-methyl-D-glucoside, α-methyl-D-mannoside, D-raffinose, D-ribose, salicin, L-sorbose, sucrose, D-trehalose, 2,3-butanediol, *meso*-erythritol, *meso*-inositol, 1,2-propanediol, D-sorbitol, and D-xylitol. Nitrate is not reduced to nitrite. H_2S is not produced. Gelatin is liquefied. Casein, DNA, elastin, esculin, and hypoxanthine are degraded, but chitin, starch, DL-tyrosine, urea, and xanthine are not. Assimilation of organic acids (acetate, benzoate, citrate, formate, malate, succinate, DL-tartrate) is not observed. Cell wall contains LL-A_2pm as the diagnostic diamino acid and glucose as the major sugar, respectively. The major menaquinone is MK-9(H_4). The phospholipid profile contains diphosphatidylglycerol, phosphatidylglycerol, phosphatidylcholine, phosphatidylinositol, phosphatidylinositol mannoside, and an unknown phospholipid. Mycolic acids are not present. The major cellular fatty acids are $C_{15:0}$ anteiso (20.4%), $C_{16:0}$ iso (18.0%), and $C_{14:0}$ iso (8.9%).

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: D8-87, DSM 45079, JBRI 2008, KCTC 19222.

Sequence accession no. (16S rRNA gene): AM422451.

4. **Jiangella muralis** Kämpfer, Schäfer, Lodders and Martin 2011, 130[VP]

mu.ra′lis. L. fem. adj. *muralis* pertaining or belonging to wall(s).

Forms mycelia-like filaments, about 1.3 µm in width. Substrate mycelium on M79 agar is white to beige, aerial mycelium is white. Gram-positive, oxidase positive (weak reaction), showing an aerobic respiratory metabolism. Good growth occurs after 3 d of incubation on tryptone soy agar, M79 agar, and nutrient agar at 25–30°C. The quinone system of 15-Je-017[T] is composed of the predominant compound menaquinone MK-9(H_4). The polar lipid profile consists of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylcholine, phosphaditylinositol, and phosphatidylinositol mannoside. Major fatty acids are $C_{15:0}$ iso, $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. Straight-chain fatty acids $C_{15:0}$, $C_{16:0}$, $C_{17:0}$, and $C_{18:0}$ are produced in minor amounts. Hydrolyzes esculin, pNP-phenyl-phosphonate, 2-deoxythymidine-5′-pNP phosphate, pNP-β-D-glucuronide, pNP-α-D-glucopyranoside, pNP-β-D-xylopyranoside, bis-pNP phosphate, pNP-phosphoryl-choline, L-alanine-pNA, and L-proline-pNA. Does not hydrolyze ONPG, pNP-β-D-glucopyranoside, and L-glutamate-gamma-3-carboxy-pNA. Utilizes (weakly) as sole source of carbon: *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, D-glucose, D-mannose, D-maltose, L-rhamnose, D-ribose, sucrose, D-trehalose, D-xylose, adonitol, D-mannitol, acetate, fumarate, DL-3-hydroxybutyrate, DL-lactate, L-malate, 2-oxoglutarate, pyruvate, L-alanine, L-aspartate, L-histidine, L-proline, and L-phenylalanine. Cannot utilize gluconate, α-D-melibiose, D-mannitol, inositol, D-sorbitol, putrescine, propionate, *cis*-aconitate, *trans*-aconitate, adipate, 4-amninobutyrate, azelate, citrate, glutarate, itaconate, mesaconate, suberate, β-alanine, L-leucine, L-ornithine, L-serine, L-tryptophane, 3-hydroxybenzoate, 4-hydroxyenzoate, and phenylacetate.

DNA G+C content (mol%): not determined.

Type strain: 15-Je-017, DSM 45357, CCM 7680.

Sequence accession no. (16S rRNA gene): FN645214, GU574121.

Genus II. **Haloactinopolyspora** Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 199^{VP}

Shun-Kun Tang, Xiao-Yang Zhi and Wen-Jun Li

ha.lo.ac.ti.no.po.ly.spo′ra. Gr. n. *hals halos* salt; Gr. n. *actis*, *actinos* a ray; Gr. adj. *poly* many; Gr. n. *spora* a seed and, in biology, a spore; N.L. fem. n. *Haloactinopolyspora* salt-loving and the many spored ray.

Gram-stain-positive, strictly aerobic, moderately halophilic filamentous actinomycete. The substrate mycelium fragments into rod-like elements, and the aerial mycelium has long spore chains and forms root-like spore heaps at maturity (Figure 130). The growth is good on GTY agar and potato agar, moderate on Czapek's agar, inorganic salts-starch agar (ISP 4), and oatmeal agar (ISP 3), weak on nutrient agar and glycerol/asparagine agar (ISP 5), but no growth is observed on yeast extract-malt extract agar (ISP 2). The color of the aerial mycelium is white and that of the substrate mycelium was white-yellow. No soluble pigments are produced.

DNA G+C content (mol%): 70–71.

Type species: **Haloactinopolyspora alba** Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 199^{VP}.

Further descriptive information

Phylogenetic analysis of the 16S rRNA gene sequence places the genus within the family *Jiangellaceae* and order *Jiangellales*. The cell-wall hydrolysates contain LL-diaminopimelate, alanine, glycine, and glutamate as the cell-wall amino acids; glucosamine, glucose, galactose, mannose, and arabinose are the major cell-wall sugars. The phospholipids are diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, one unknown phosphoglycolipid, one unknown phospholipid, and one unknown glycolipid. The predominant menaquinone is MK-9(H_4). The major fatty acids are $C_{16:0}$ iso, $C_{15:0}$ anteiso, and $C_{17:0}$ anteiso.

Isolation procedures

The only species was isolated from a soil sample collected from Qijiaojing Lake, which is a salt lake in Xinjiang Province, northwest China (GPS coordinates for the sampling site are 43°26′48″N 91°29′13″E), after 3 weeks incubation at 37°C on cellulose-casein multi-salt (CCMS) medium described by Tang et al. (2008).

Maintenance procedures

The type strain is maintained on GTY agar slants (Tang et al., 2011) containing 15% (w/v) NaCl at 4°C and in 20% (v/v) glycerol suspensions of well grown liquid cultures and stored frozen at –80°C or in liquid nitrogen.

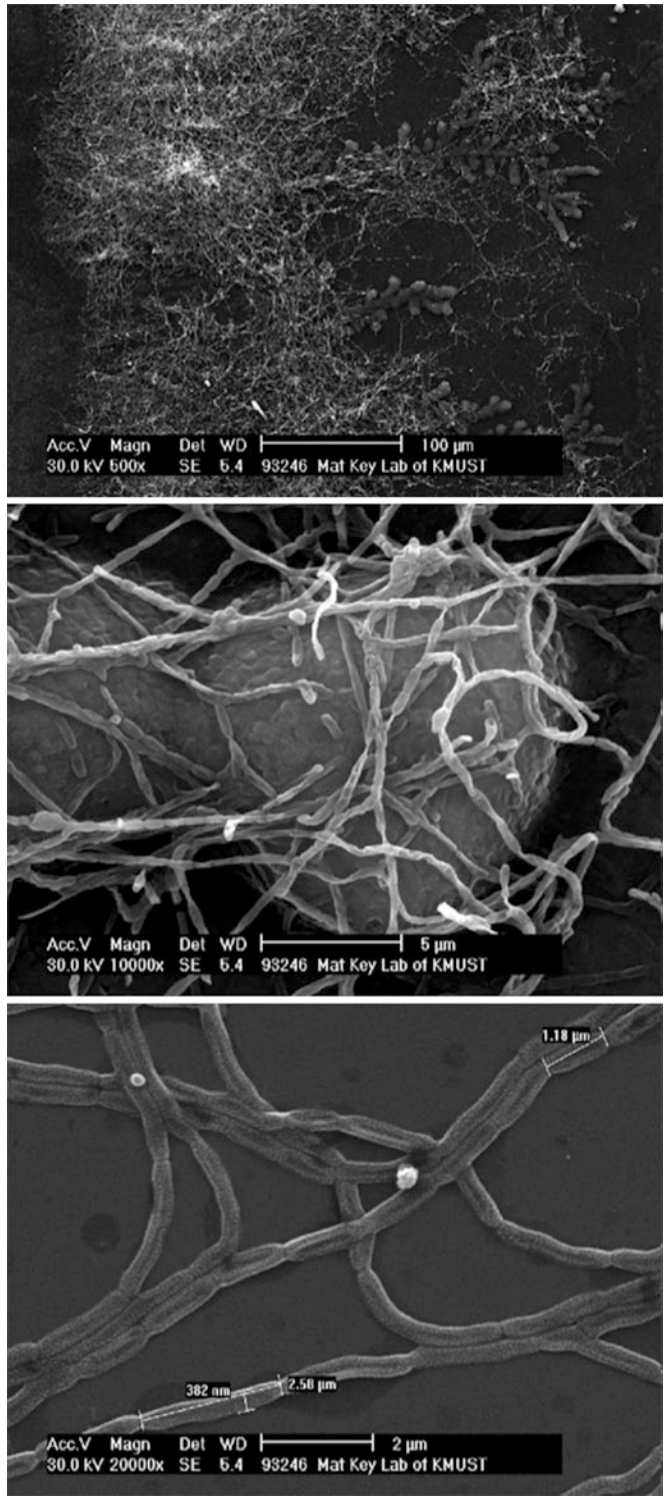

FIGURE 130. Scanning electron micrograph of spore chains of *Haloactinopolyspora alba* YIM 93246^{T} grown on GTY medium including 10% (w/v) NaCl for 28 d at 37°C; (top) aerial mycelia and root-like spore heap; (middle) long spore chains and spore heap; (bottom) fragmented substrate mycelia.

List of species of the genus *Haloactinopolyspora*

1. **Haloactinopolyspora alba** Tang, Zhi, Wang, Shi, Lou, Xu and Li 2011, 199[VP]

al′ba. L. fem. adj. *alba* white.

Displays the following properties in addition to those described for the genus. Growth occurs at 15–45°C, pH 4.0–9.0, and 7–23% (w/v) NaCl. Optimal growth occurs at 28–37°C, pH 7.0–8.0, and 10–15% (w/v) NaCl, and no growth occurs in the absence of NaCl. Esculin, Tweens 40, 60, and 80 are degraded, but casein, starch, dextrin, chitin, Tween 20, and urea are not. Tests for milk peptonization and coagulation are positive, but gelatin liquefaction, nitrate reduction, starch hydrolysis, H_2S, and melanin production are negative. Cellobiose, dulcitol, D-fructose, inositol, lactose, maltose, D-mannose, rhamnose, sucrose, sorbitol, and trehalose, are utilized as sole carbon sources, while erythritol, galactose, D-glucose, glycerol, glycine, mannitol, raffinose, D-ribose, sodium propionate, trisodium citrate, xylitol, and D-xylose are not. Adenine, L-arginine, L-histidine, hypoxanthine, L-lysine, L-methionine, L-proline, L-serine, and L-threonine are utilized as sole nitrogen sources, whereas growth on L-alanine, D-arabinose, L-asparagine, L-phenylalanine, L-tyrosine, and xanthine is not observed. In the API ZYM system, alkaline phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), α- and β-galactosidase, α- and β-glucosidase, α-mannosidase, and *N*-acetyl-β-glucosaminidase are positive; acid phosphatase, α-chymotrypsin, cystine arylamidase, α-fucosidase, β-glucuronidase, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase are negative.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: YIM 93246, DSM 45211, KCTC 19409.

Sequence accession no. (16S rRNA gene): FJ969846.

Order IX. **Kineosporiales** ord. nov.

Peter Kämpfer

Ki.ne.o.spo.ri′a.les. N.L. fem. n. *Kineosporia* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Kineosporales* the *Kineosporia* order.

The delineation of the order is based on 16S rRNA gene sequence analysis and contains only the family *Kineosporiaceae* (Zhi et al., 2009). The pattern of 16S rRNA signature nucleotides that defines the order is identical to that of the family *Kineosporiaceae*. The pattern of 16S rRNA signatures consists of nucleotides at positions 127:234 (A–U), 142:221 (C–U), 598:640 (U–G), 840:846 (A–C), 845 (A), 986:1218 (A–U), 1163:1173 (G–U), 1164:1172 (G–C), and 1165:1171 (G–A) according to Zhi et al. (2009) proposed for the *Kineosporiineae*.

Type genus: **Kineosporia** Pagani and Parenti 1978, 401[AL].

Family I. **Kineosporiaceae** Zhi, Li and Stackebrandt 2009, 596[VP]

Philippe Normand and David R. Benson

Ki.ne.o.spo.ri.a.ce′a.e. N.L. fem. n. *Kineosporia* type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Kineosporiaceae* the *Kineosporia* family.

The family *Kineosporiaceae* was proposed in the taxonomic outline to the 2nd edition of *Bergey's Manual of Systematic Bacteriology*, based on a heat-map analysis of aligned 16S rRNA sequences (Garrity et al., 2002; Lilburn and Garrity, 2004), to include initially three genera, *Kineosporia*, *Cryptosporangium*, and *Kineococcus*. However, this outline did not comprise a formal description. *Kineosporia* was included in the 1st edition of *Bergey's Manual of Systematic Bacteriology* in section 29 "Streptomycetes and related genera" (Locci, 1989) alongside *Sporichthya*. *Kineococcus* was described later in 1993 (Yokota et al., 1993), whereas *Cryptosporangium* was described in 1998 (Tamura et al., 1998). In the course of this work, it was noticed that the newly created genus *Quadrisphaera* (Maszenan et al., 2005) also belonged to this family; it is thus included here. Conversely, inclusion of the genus *Cryptosporangium* in the family *Kineosporiaceae* is debatable (Figure 102). Most recently, the family *Kineosporiaceae* was proposed to include only the genera *Kineosporia*, *Kineococcus*, and *Quadrisphaera*, and *Cryptosporangium* was transferred it to the suborder *Frankineae*, now the order *Frankiales* (Zhi et al., 2009). While the genus *Cryptosporangium* is now treated in the order Frankiales and family *Cryptosporangiaceae*, it does possess some chemotaxonomic similarities to the *Kineosporiaceae* (Table 67). The family comprises a group of diverse aerobic mesophilic microorganisms, isolated from soils, plant materials, and, in one case, from a radioactive work area, that have complex morphology. It includes the three bacterial genera *Kineosporia*, *Kineococcus*, and *Quadrisphaera*. Comparative phenotypic characteristics of members of the family *Kineosporiaceae* and the genus *Cryptosporangium* are given in Table 67. The DNA G+C content ranges from 68 to 76.6 mol%, making this taxon unusual. The cell wall contains mostly *meso*-DAP, menaquinonones are composed of 9(H_4), 9(H_2), 9(H_6), and 8(H_2), and fatty acids comprise $C_{16:0}$, $C_{18:1}$, and $C_{15:0}$ anteiso. With the removal of *Cryptosporangium*, the group forms a coherent clade upon 16S rRNA gene sequence analysis (Figure 102).

DNA G+C content (mol%): 68–76.6.

Type genus: **Kineosporia** Pagani and Parenti 1978, 401[AL] emend. Itoh, Kudo, Parenti and Seino 1989, 172 emend. Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1253.

Genus I. **Kineosporia** Pagani and Parenti 1978, 401[AL] emend. Itoh, Kudo, Parenti and Seino 1989, 172 emend. Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1253

Philippe Normand and David R. Benson

Ki.ne.o.spo′ri.a. Gr. n. *kinesis* motion; Gr. fem. n. *spora* a seed; N.L. fem. n. *spora* a spore; N.L. fem. n. *Kineosporia* an organism that has motile spores.

Aerobic, Gram-stain-positive, and non-acid-fast. Colonies on agar medium lack aerial mycelia, form central projections with radiating vegetative hyphae (Figure 131), and are occasionally accompanied by bunches of spore clusters in the agar. Mature colonies have a gelatinous matrix that confers a glossy appearance. Spores, which are spherical to ovoid or pyriform with a long axis of 1±2 µm, are **catenated** around the central projection or are located singly or in aggregates at the tips of hyphae. The **spores are motile** with polar tufts of flagella (Figure 132). The peptidoglycan contains either almost equivalent amounts of LL- and *meso*-DAP or mainly LL- or *meso*-DAP. The spores contain predominantly *meso*-DAP accompanied by glycine. The whole cultured organism contains galactose, glucose, mannose, and ribose. In addition to these sugars, rhamnose and 3-*O*-methylrhamnose may be present. Phosphatidylcholine is a diagnostic phospholipid and MK-9(II,III-H_4) is present as a major component. The cellular fatty acid profile is composed mainly of n-hexadecanoic acid and n-octadecenoic acid, and lacks iso- and anteiso-branched fatty acids. 10-Methyloctadecanoic acid and 2-hydroxyhexadecanoic acids are also present in some strains. Mycolic acids are absent.

DNA G+C content (mol%): 69–71.

Type species: **Kineosporia aurantiaca** Pagani and Parenti 1978, 401[AL].

List of species of the genus *Kineosporia*

1. **Kineosporia aurantiaca** Pagani and Parenti 1978, 401[AL]

au.ran.ti.a′ca. N.L. fem. adj. *aurantiaca* of an orange color.

This species was the first species of the genus described and remained the only one for several years.

Colonies are pleomorphic on all media, particularly on yeast extract-malt extract agar. The wet, glossy appearance, evident after 7 d, is due to abundant formation of sporangia. Growth occurs by the spreading of the vegetative mycelium into the agar and by thickening of the layer formed by the hyphae. Small colonies of 0.5–2 mm in diameter are formed and are colorless for the first few days of growth, turning cream to orange thereafter. Colonial morphology is variable even on the same agar plate, ranging from conical-crateriform to cerebriform. Vegetative mycelium consists of small (1 µm in diameter), slightly branched hyphae. Aerial mycelium has not been observed on any medium tested. Sporangia appear as elongated, club-shaped vesicles, 1–2 µm in diameter, borne at the terminal end of the vegetative hyphae. Each sporangium contains a single spore. The spores are pleomorphic, their shape ranging from nearly spherical to oval or pyriform. The long axes of the spores vary between 1 and 2 µm. Upon sporangium dehiscence, spores are motile for several hours, with a polar tuft of flagella. Gram-stain-positive and non-acid-fast. The peptidoglycan of the cell wall contains varying amounts of LL-DAP, a very small amount of *meso*-DAP, and glycine. Traces of lysine are also found. Aerobic. Chemoorganotrophic, using a range of simple sugars. Optimum temperature for growth and sporulation is 20–30°C, with no growth at or above 37°C. Optimum pH 7.0. Nonpathogenic to mice.

Source: occurs free-living in soil.

DNA G+C content (mol%): 68–71 (reverse HPLC; Tamaoka and Komagata, 1984).

Type strain: ATCC 29727, DSM 43858, NBRC 14067, JCM 3230, NRRL B-16913, VKM Ac-702.

Sequence accession no. (16S rRNA gene): AB003931.

2. **Kineosporia mikuniensis** Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1253[VP]

mi.ku.ni.en′sis. N.L. fem. adj. *mikuniensis* of or belonging to Mt Mikuni, Gumma Prefecture, Japan, the location from which the type strain was isolated.

Substrate mycelia are orange to light brown (especially on yeast extract-starch agar). Produces faint yellowish diffusible pigments in oatmeal agar. Decomposes casein and urea, but not esculin, hypoxanthine, tyrosine, or xanthine. Utilizes L-arabinose, D-arabitol, cellobiose, D-fructose, D-galactose, D-glucose, *myo*-inositol, D-lactose, maltose, D-mannitol, melezitose, melibiose, methyl α-D-glucoside, L-rhamnose, D-ribose, salicin, starch, trehalose, and D-xylose as sole carbon sources, but not adonitol, i-erythritol, raffinose, D-sorbitol, L-sorbose, or xylitol. Utilizes fumaric acid, L-malic acid, and succinic acid, but not benzoic acid, citric acid, mucic acid, oxalic acid, or L-tartaric acid. Produces acid from L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, *myo*-inositol, L-rhamnose, sucrose, and D-xylose, but not adonitol, i-erythritol, melezitose, or D-sorbitol. Does not grow in the presence of 1% (w/v) NaCl. Mesophilic. Contains a major amount of *meso*-DAP in the cell wall. Contains neither rhamnose nor 3-*O*-methylrhamnose in the whole-cell hydrolyzate. Monotypic.

Source: sphagnum, Mt Mikuni, Gumma Prefecture, Japan.

DNA G+C content (mol%): 69 (reverse HPLC; Tamaoka and Komagata, 1984).

Type strain: I-463, JCM 9961.

Sequence accession no. (16S rRNA gene): not available.

3. **Kineosporia rhamnosa** Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1254[VP]

rham.no′sa. N.L. fem. adj. *rhamnosa* (from the Greek *rhamnos* a branch) pertaining to rhamnose.

Substrate mycelia are orange to light brown (especially on yeast extract-starch agar). Does not produce any diffusible pigments in yeast extract-starch or oatmeal agar media. Decomposes casein, DNA, and urea, but not esculin, hypoxanthine, tyrosine, or xanthine. Utilizes cellobiose, D-fructose, D-galactose, D-glucose, *myo*-inositol, maltose, D-mannitol, L-rhamnose, D-sorbitol, starch, and D-xylose as sole carbon sources, but not adonitol, D-arabitol, i-erythritol, D-lactose, melezitose, melibiose, methyl α-D-glucoside, D-ribose, salicin, L-sorbose, trehalose, or xylitol. Utilizes fumaric acid, L-malic acid, and succinic acid, but not benzoic acid, citric acid, mucic acid, oxalic acid, or L-tartaric acid. Produces acid from L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, *myo*-inositol, L-rhamnose, D-sorbitol, sucrose, and D-xylose, but not from adonitol, i-erythritol, or melezitose. Does not grow in the presence of 2% (w/v) NaCl. Mesophilic. Contains a major amount of *meso*-DAP in the cell wall. Contains rhamnose and 3-*O*-methyl-rhamnose in the whole-cell hydrolyzate.

Source: leaves of cat-tail (*Typha latifolia*), pond in Saitama, Japan.

DNA G+C content (mol%): 68–69 (reverse HPLC; Tamaoka and Komagata, 1984).

Type strain: I-132, JCM 9954.

Sequence accession no. (16S rRNA gene): AB003935.

4. **Kineosporia rhizophila** Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1253[VP]

rhi.zo′phi.la. Gr. n. *rhiza* root; N.L. fem. adj. *phila* (from Gr. fem. adj. *philê*) friend, loving; N.L. fem. adj. *rhizophila* root-loving.

Substrate mycelia are orange to light brown (especially on yeast extract-starch agar). Produces faint red diffusible pigments on yeast extract-starch agar. Decomposes casein, DNA, testosterone, and urea, but not adenine, esculin, hypoxanthine, tyrosine, or xanthine. Utilizes L-arabinose, D-arabitol, cellobiose, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannitol, melezitose, melibiose, raffinose, L-rhamnose, D-ribose, salicin, starch, sucrose, trehalose, and D-xylose as sole carbon sources, but not adonitol, dulcitol, i-erythritol, *myo*-inositol, methyl α-D-glucoside, D-sorbitol, L-sorbose, or xylitol. Utilizes fumaric acid, L-malic acid, and succinic acid, but not benzoic acid, citric acid, mucic acid, oxalic acid, or L-tartaric acid. Produces acids from L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, melezitose, L-rhamnose, sucrose, and D-xylose, but not from adonitol, i-erythritol, *myo*-inositol, or D-sorbitol. Tolerates up to 4% (w/v) NaCl. Mesophilic. Contains a major amount of

meso-DAP in the cell wall. Contains neither rhamnose nor 3-*O*-methyl-rhamnose in the whole-cell hydrolyzate.

Source: root of galingale (*Cyperus microiria*), Saitama, Japan.

DNA G+C content (mol%): 70 (reverse HPLC; Tamaoka and Komagata, 1984).

Type strain: I-449, JCM 9960.

Sequence accession no. (16S rRNA gene): AB003933.

5. **Kineosporia succinea** Kudo, Matsushima, Itoh, Sasaki and Suzuki 1998, 1253[VP]

suc.ci′ne.a. L. fem. adj. *succinea* of amber, intended to mean of an amber color.

Substrate mycelia are orange to light brown (especially on yeast extract-starch agar). Produces faint yellow diffusible pigments on oatmeal agar. Decomposes casein, DNA, hypoxanthine, testosterone, and urea, but not adenine, esculin, tyrosine, or xanthine. Utilizes L-arabinose, D-arabitol, cellobiose, dulcitol, D-fructose, D-galactose, D-glucose, D-lactose, maltose, D-mannitol, melezitose, melibiose, L-rhamnose, D-ribose, salicin, starch, sucrose, trehalose, and D-xylose as sole carbon sources, but not adonitol, i-erythritol, methyl α-D-glucoside, raffinose, L-sorbose, or xylitol. Utilizes fumaric acid, L-malic acid, and succinic acid, but not benzoic acid, citric acid, mucic acid, oxalic acid, or L-tartaric acid. Produces acid from L-arabinose, cellobiose, D-fructose, D-galactose, D-glucose, L-rhamnose, sucrose, and D-xylose, but not from adonitol, i-erythritol, *myo*-inositol, melezitose, or D-sorbitol. Tolerates up to 4% (w/v) NaCl. Mesophilic. Contains almost the same amount of LL- and *meso*-DAP or a major amount of LL-DAP in the cell wall. Whole-cell hydrolyzate does not contain rhamnose or 3-*O*-methyl-rhamnose.

Source: fallen leaves, Saitama, Japan.

DNA G+C content (mol%): 70–71 (reverse HPLC; Tamaoka and Komagata, 1984).

Type strain: I-273, JCM 9957.

Sequence accession no. (16S rRNA gene): AB003932.

Genus II. **Kineococcus** Yokota, Tamura, Nishii and Hasegawa 1993, 56[VP]

Philippe Normand and David R. Benson

Ki.ne.o.coc′cus. Gr. n. *kinesis* motion; N.L. masc. n. *coccus* from Gr. masc. n. *kokkos* a grain, seed; N.L. masc. n. *Kineococcus* a motile coccus.

Cells are spherical, 1.0–1.5 µm in diameter, and occur in pairs, **tetrads, or clusters**. Motile. The **motile cells have tufts of flagella**. Endospores are not formed. Gram-stain-positive. Colonies are circular and rough and may be cream colored to orange. Strictly aerobic. Catalase- and urease-positive. Oxidase-negative. Does not reduce nitrate to nitrite. Acid is produced from glucose and some other sugars. Esculin is hydrolyzed. Starch, gelatin, and casein are not hydrolyzed. The optimum growth temperature is 27°C. The cell wall peptidoglycan contains *meso*-DAP, alanine, and glutamic acid. The major menaquinone is MK-9(H_2). Mycolic acid is not present. The major cellular fatty acid is $C_{15:0}$ anteiso. Diphosphatidylglycerol, phosphatidylglycerol, and unidentified glycolipids are present as polar lipids.

The phylogeny of the genus *Kineococcus* based on 16S rRNA gene sequencing is dubious (Figure 102) given that the topology varies with the algorithm used; in particular, *Kineococcus marinus* is either positioned at the root of the branch leading to the species *Kineococcus radiotolerans* and *Kineococcus aurantiacus*, or else on a distinct branch together with *Quadrisphaera granulorum*. This uncertainty will likely be resolved by further studies based on several genes, which will become possible with the availability of complete genomes and with consideration of more physiological features.

DNA G+C content (mol%): 73.9–74.2.

Type species: **Kineococcus aurantiacus** Yokota, Tamura, Nishii and Hasegawa 1993, 56[VP].

Differentiation of the species of the genus *Kineococcus*

Discriminating features of the three species of the genus *Kineococcus* are listed in Table 69.

List of species of the genus *Kineococcus*

1. **Kineococcus aurantiacus** Yokota, Tamura, Nishii and Hasegawa 1993, 56[VP]

au.ran.ti.a′cus. N.L. n. *aurantium* generic name of the orange; N.L. masc. adj. *aurantiacus* orange-colored.

Morphology is as described for genus (Yokota et al., 1993). Cells are spherical and 1.0–1.5 µm in diameter and occur in pairs, tetrads, or clusters (Figure 133). Motile. The motile cells have tufts of flagella. Endospores are not formed. Gram-stain-positive. Colonies are circular, rough, and may be cream colored to orange. Strictly aerobic. Catalase- and urease-positive. Oxidase-negative. Does not reduce nitrate to nitrite. Acid is produced from D-glucose, D-xylose, D-fructose, sucrose, and L-arabinose. Acid is not produced from glycerol, D-ribose, D-arabinose, raffinose, maltose, D-galactose, D-mannose, inositol, L-rhamnose, mannitol, or trehalose. Does not hydrolyze esculin, starch, gelatin, or casein. The optimum growth temperature is 28°C. Chemical characteristics, such as amino acid composition of the cell wall peptidoglycan, menaquinone system, mycolic acids, cellular fatty acids, and polar lipids, are the same as given above for the genus.

Source: isolated from soil.

DNA G+C content (mol%): 73.9 (HPLC; Mesbah and Whitman, 1989).

Type strain: RA 333, ATCC 51238, CIP 105426, DSM 7487, NBRC 15268.

Sequence accession no. (16S rRNA gene): AB007420.

2. **Kineococcus marinus** Lee 2006, 1282[VP]

ma.ri′nus. L. masc. adj. *marinus* of the sea, the origin of the sample from which the type strain was isolated.

Aerobic, motile, non-spore-forming, oxidase-negative, catalase-positive, Gram-stain-positive cocci. Cells occur singly, in pairs, or in clusters (Figure 134). Forms capsular polysaccharide-like substances on most solid media. Colonies are circular, smooth, convex, and deep orange in color. Glucose fermentation, H_2S production, and nitrate

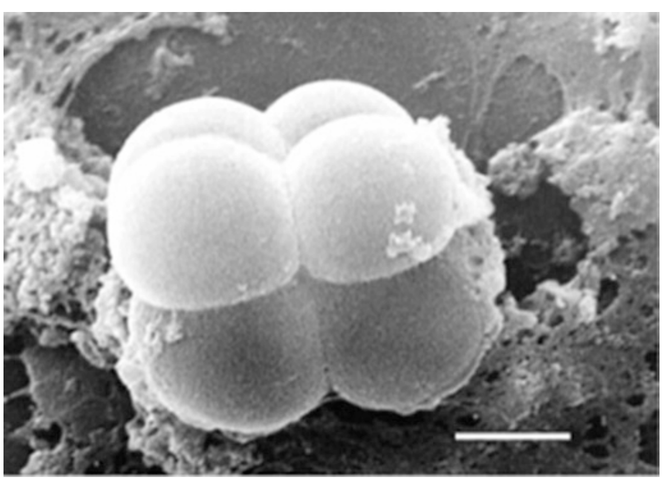

FIGURE 133. Cluster of cells of *Kineococcus aurantiacus* NBRC 15268^T. (From the Digital Atlas of Actinomycetes; photo by T. Tamura, T. Hasegawa and A. Yokota, www.nih.go.jp/saj/DigitalAtlas/; copyright owned by The Society for Actinomycetes, Japan.)

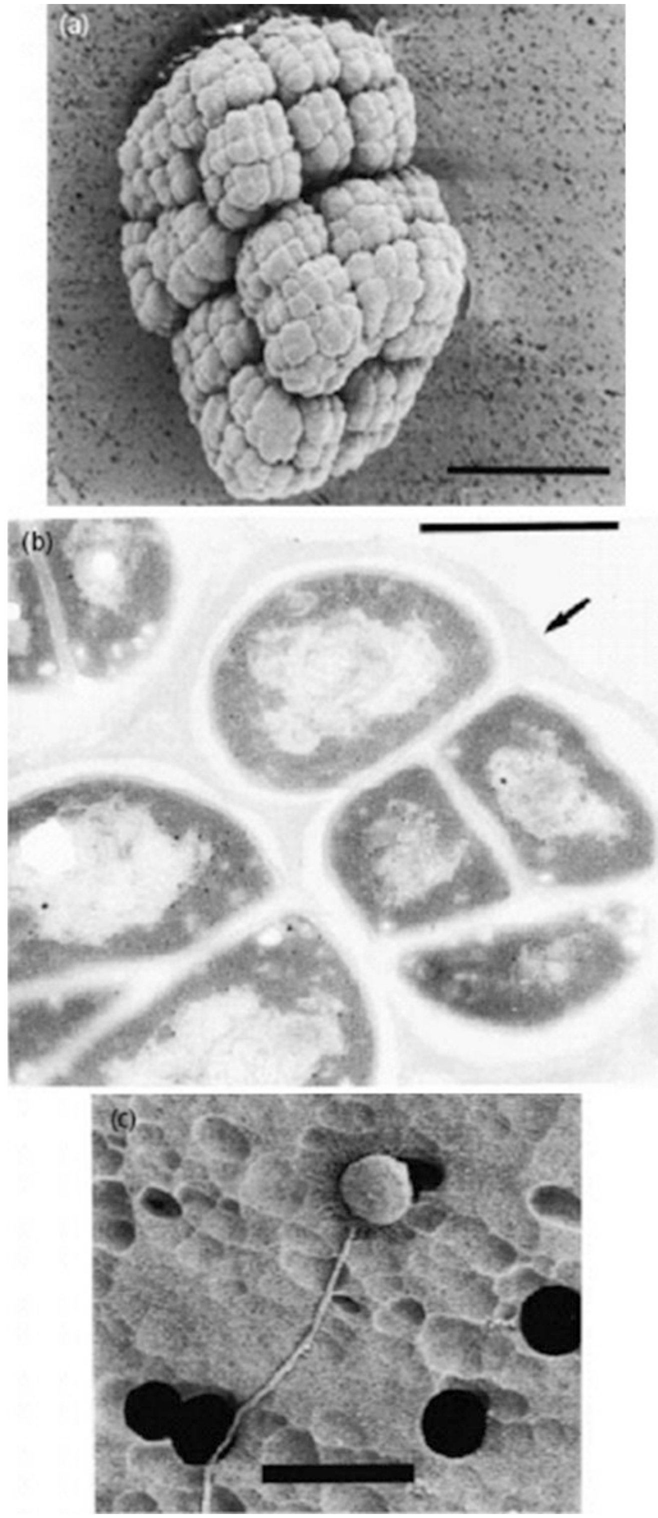

FIGURE 134. (a) Scanning electron micrograph of *Kineococcus radiotolerans* SRS30216^T cultured on PTYG agar (pH 7.0) showing clusters formed by growing cells; bar = 1 µm. (b) Transmission electron micrograph of a thin section of cells of strain SRS30216^T; the *arrow* shows the presence of extracellular matrix; bar = 1 µm. (c) Scanning electron micrograph of a motile cell of strain SRS30216^T exhibiting a single flagellum; bar = 2 µm. (Reprinted with permission from Phillips et al., 2002. Int. J. Syst. Evol. Microbiol. *52*: 933–938.)

reduction are not observed. The temperature range for growth is 4–37°C with optimum growth at 30°C. No growth is observed at or above 40°C. Growth occurs at pH 5.1–10.1, with optimum growth at pH 7.1. β-Galactosidase is present, but urease activity is not detected. DNA, esculin, gelatin, and starch are hydrolyzed, but casein and elastin are not. Salt is required for growth; good growth occurs in 1–4% NaCl, moderate growth in 5–8% NaCl, and poor growth in 9% NaCl. α-Cyclodextrin, β-cyclodextrin, dextrin, glycogen, L-arabinose, D-arabitol, arbutin, cellobiose, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, D-gluconic acid, α-D-glucose, *myo*-inositol, α-D-lactose, lactulose, maltose, D-mannitol, D-mannose, melezitose, methyl β-D-galactoside, 3-methyl D-glucoside, methyl α-D-glucoside, methyl α-D-mannoside, palatinose, D-psicose, raffinose, L-rhamnose, D-ribose, salicin, sedoheptulosan, stachyose, sucrose, D-tagatose, trehalose, turanose, xylitol, D-xylose, acetic acid, α- and β-hydroxybutyric acids, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, L-lactic acid, D- and L-malic acid, monomethyl succinate, propionic acid, succinamic acid, L-alaninamide, D-and L-alanine, L-asparagine, glycyl L-glutamic acid, L-serine, glycerol, adenosine, 2′-deoxyadenosine, inosine, AMP, TMP, UMP, D-fructose 6-phosphate, α-D-glucose 1-phosphate, and DL-α-glycerol phosphate are utilized as sole carbon and energy sources for growth. The following substrates are not utilized: inulin, mannan, Tweens 40 and 80, *N*-acetyl-D-glucosamine, *N*-acetyl-β-D-mannosamine, amygdalin, maltotriose, melibiose, methyl α-D-galactoside, methyl β-D-glucoside, D-sorbitol, γ-hydroxybutyric acid, D-lactic acid methyl ester, methyl pyruvate, succinic acid, *N*-acetyl-L-glutamic acid, L-alanyl glycine, L-glutamic acid, L-pyroglutamic acid, putrescine, 2,3-butanediol, thymidine, uridine, and D-glucose 6-phosphate. The diagnostic diamino acid of the peptidoglycan is *meso*-DAP. Whole-cell hydrolyzates contain arabinose and galactose as characteristic sugars. The glycan moiety of the murein structure is acetylated. Mycolic acids are not detected. The predominant menaquinone is MK-9(H_2). Polar lipids contain phosphatidylglycerol and phosphatidylinositol, thus constituting a phospholipid-type PI pattern *sensu* Lechevalier et al. (1981). The major cellular fatty acid is 12-methyltetradecanoic acid ($C_{15:0}$ anteiso).

Source: the type strain was isolated from a sediment sample taken off the coast of Jeju, Republic of Korea.

DNA G+C content (mol%): 76.6 (HPLC).

Type strain: KST3-3, KCCM 42250, NRRL B-24439.

Sequence accession no. (16S rRNA gene): DQ200982.

3. **Kineococcus radiotolerans** Phillips, Wiegel, Berry, Fliermans, Peacock, White and Shimkets 2002, 937[VP]

ra.di.o.to.le′rans. L. n. *radiatio* radiation; N.L. pref. *radio*- pertaining to radiation; L. part. adj. *tolerans* tolerating; N.L. part. adj. *radiotolerans* radiation-tolerating.

Morphology is as described for genus. Cells are cocci, 1.0–1.5 µm in diameter. Cells occur in pairs, tetrads, and large clusters. Colonies are circular, rough, and orange-pigmented. Gram-stain-positive. Cells are motile and produce polar flagella. Catalase-positive. Urease and oxidase tests are negative. A variety of carbon sources is used including glucose, galactose, L-arabinose, sucrose, mannose, xylose, glycerol, mannitol, inositol, and sorbitol, but not raffinose, rhamnose, lactose, citrate, ribose, or maltose. The major fatty acid produced is $C_{15:0}$ anteiso (approx. 90%). Growth occurs at temperatures between 11 and 41°C, between pH 5 and 9, and at NaCl concentrations up to and including 5%. Desiccation-tolerant (100% cell survival after 14 d). Radiation-resistant (>10% cell survival at 3 kGy). An orange pigment, soluble in methanol, with an absorption spectrum with peaks at 444, 471, and 501 nm, is produced.

Source: the type and only strain was isolated from the Savannah River Site in Aiken, South Carolina, USA.

DNA G+C content (mol%): 74.2 (complete genome sequence analysis; http://genome.ornl.gov/microbial/krad/).

Type strain: SRS30216, ATCC BAA-149, DSM 14245.

Sequence accession no.: NZ_AAEF02000006 (complete genome of strain SRS30216[T]).

Genus III. **Quadrisphaera** Maszenan, Tay, Schumann, Jiang and Tay 2005, 1774[VP]

Philippe Normand and David R. Benson

Qua.dri.spha′e.ra. L. pref. numer. adj. *quadr*- four; L. fem. n. *sphaera* a ball, a globe, a sphere; N.L. fem. n. *Quadrisphaera* fourfold balls, coccus in tetrad.

Gram-positive, non-spore-forming cocci, 1.2–3.0 µm in diameter, **occurring in tetrad** arrangements (Figure 135), fitting the morphological description of tetrad-forming organisms described previously in sludge-inhabiting microbes (Cech and Hartman, 1990). MK-8(H_2) is the predominant menaquinone. The phylogenetic position based on 16S rRNA gene sequence analysis (Figure 102) should be in the family *Kineosporiaceae*.

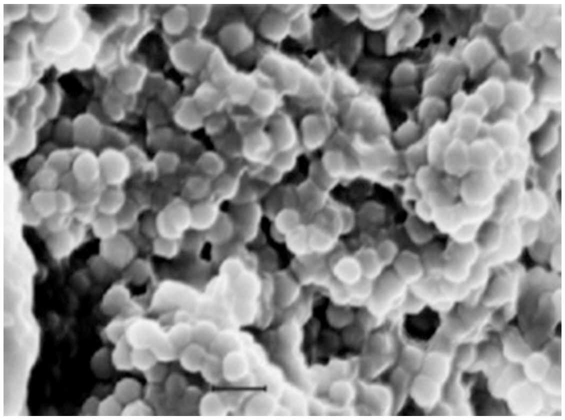

FIGURE 135. Scanning electron micrograph of *Quadrisphaera granulorum* strain AG019[T] showing cocci in tetrad and cluster arrangements. Bar = 3 µm. (Reprinted with permission from Maszenan et al., 2005. Int. J. Syst. Evol. Microbiol. *55*: 1771–1777.)

DNA G+C content (mol%): 75.

Type species: **Quadrisphaera granulorum** Maszenan, Tay, Schumann, Jiang and Tay 2005, 1774[VP].

Further descriptive information

The bacterial genus *Quadrisphaera* (Maszenan et al., 2005) was created to accommodate an isolate obtained from granules suspended in a batch-fed activated sludge reactor. This isolate was given species and genus rank and deemed to be most closely related to members of the family *Frankiaceae*, and later on positioned in the family *Nakamurellaceae* by the NCBI Taxonomy Browser (http://www.ncbi.nlm.nih.gov/Taxonomy/tax.html/) as well as in the TOBA (http://www.taxonomicoutline.org/). The present study however, based on an analysis of 16S rRNA gene sequences, positioned it close to the family *Kineosporiaceae* with a bootstrap value of 99% (Figure 102).

List of species of the genus *Quadrisphaera*

1. **Quadrisphaera granulorum** Maszenan, Tay, Schumann, Jiang and Tay 2005, 1774[VP]

gra.nu.lo′rum. L. gen. pl. n. *granulorum* from or of granules.

In addition to characteristics given in the genus description, also utilizes α-cyclodextrin, α-DL-glycerol phosphate, Tween 40, arbutin, glucose 1-phosphate, Tween 80, glucose 6-phosphate, adonitol, L-arabinose, D-arabitol, glucuronamide, cellobiose, D-psicose, D-mannitol, melezitose, melibiose, L-serine, methyl β-D-glucoside, psicose, D-xylose, methyl pyruvate, pyruvate, 2-aminoethanol, monomethyl succinate, glycerol, L-serine, turanose, and glycerol. It cannot metabolize the following: β-cyclodextrin, dextrin, glycogen, inulin, mannan, *N*-acetyl-D-galactosamine, *N*-acetylglucosamine, *N*-acetylmannosamine, amygdalin, D-arabitol, cellobiose, i-erythritol, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, D-glucuronic acid, α-D-glucose, *myo*-inositol, α-D-lactulose, α-lactose, maltose, D-mannitol, D-mannose, melezitose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl glucose, methyl α-D-glucoside, methyl β-D-glucoside, methyl α-D-mannoside, palatinose, raffinose, L-rhamnose, salicin, sedoheptulosan, D-sorbitol, stachyose, sucrose, trehalose, xylitol, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, *cis*-aconitic acid, citric acid, formic acid, D-galactonic acid lactone, itaconic acid, malonic acid, quinic acid, D-saccharic acid, sebacic acid, lactamide, D-lactic acid methyl ester, D-malic acid, L-malic acid, propionic acid, succinamic acid, succinic acid, *N*-acetylglutamic acid, bromosuccinic acid, alaninamide, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, glycyl-L-glutamic acid, L-pyroglutamic acid, putrescine, 2,3-butanediol, glycyl-L-aspartic acid, L-histidine, hydroxyl-L-proline, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglutamic acid, D-serine, L-threonine, DL-carnitine, γ-aminobutyric acid, adenosine, 2′-deoxyadenosine, inosine, thymidine, uridine, AMP, TMP, UMP, phenylethylamine, or putrescine. The following acid and acid derivatives are utilized: glucuronic acid, α-ketobutyric acid, α-ketovaleric acid, DL-lactic acid, L-aspartic acid, L-glutamic acid, urocanic acid, and pyruvic acid. The following enzyme activities are detected: esterase, esterase lipase, leucine arylamidase, valine arylamidase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase, and β-glucosidase. The following enzyme activities are not detected: alkaline phosphatase, lipase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, urease, tryptophan deaminase, and gelatinase. Does not produce H_2S or indole. Voges–Proskauer-negative. Does not produce acetoin. Does not reduce nitrate to nitrite. Catalase-positive, but oxidase-negative (Maszenan et al., 2005).

Source: aerobic granules such as those used in activated sludge reactors.

DNA G+C content (mol%): 75 (reverse HPLC; Schumann et al., 1997).

Type strain: AG019, ATCC BAA-1104, DSM 44889.

Sequence accession no. (16S rRNA gene): AY831385.

Order X. **Micrococcales** Prévot 1940, 223[AL]

Hans-Jürgen Busse

Mi.cro.coc.ca′les. N.L. fem. n. *Micrococcus* type genus of the order; suff. -*ales* ending to denote an order; N.L. fem. pl. n. *Micrococcales* the *Micrococcus* order.

Representatives of the order are characterized by a pattern of 16S rRNA signatures consisting of nucleotides at positions 127:234 (A–U), 598:642 (U–A), 657:749 (U–A), 953:1228 (G–C), and 1362 (A) as proposed for the suborder *Micrococcineae* (Stackebrandt et al., 1997; Zhi et al., 2009). Quinone systems are composed of menaquinones with 6–14 isoprenoic units in the side chain and one or two subunits may be saturated.

Type genus: **Micrococcus** Cohn 1872, 151[AL] emend. Stackebrandt, Koch, Gvozdiak and Schumann 1995, 691 emend. Wieser, Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax and Busse 2002, 635.

Further descriptive information

The order is formed by elevation of the suborder *Micrococcineae* of the class *Actinobacteria* as described by Stackebrandt et al. (1995) in the comprehensive study on Gram-stain-positive bacteria with a high DNA G+C content. The class *Actinobacteria* was proposed on the basis of phylogenetic relatedness and presence of signature nucleotides in the 16S rRNA gene sequences. The order consists of the families *Micrococcaceae*, *Brevibacteriaceae*, *Cellulomonadaceae*, *Dermabacteraceae*, *Dermatophilaceae*, *Intrasporangiaceae*, *Jonesiaceae*, *Microbacteriaceae*, *Promicromonosporaceae* (Stackebrandt et al., 1997), *Bogoriellaceae*, *Dermacoccaceae*, *Rarobacteraceae*, *Sanguibacteraceae* (Stackebrandt and Schumann, 2000), and *Beutenbergiaceae* (Hamada et al., 2009; Zhi et al., 2009). Also the family *Yaniellaceae* (Li et al., 2008), the replacement for the illegitimate name *Yaniaceae* (Li et al., 2005) was considered to be a member of this taxon. However, it was recently shown that the 16S rRNA signature nucleotide patterns of the two representatives, *Yaniella halotolerans* and *Yania flava*, correspond to the pattern defining the family *Micrococcaceae* (except an A in position 196; Zhi et al., 2009). From these observations Yassin et al. (2011) concluded that a separate family for the genus *Yaniella* was not justified and proposed to transfer the genus to the family *Micrococcaceae*. In this volume, the family *Ruaniaceae*, which is composed of the genera *Ruania* (Gu et al., 2007) and *Haloactinobacterium* (Tang et al., 2010), is also assigned to this order. Common to all representatives of the order, as well as other actinobacteria, is the presence of menaquinones as respiratory quinones. The length of the isoprenoid side chains varies (6–14 units). The menaquinones in the majority of taxa within this order (exclusive of the *Microbacteriaceae*) have 7- to 9-unit side chains, but some species exhibit a menaquinone with 10 isoprenoic units and one or two isoprenoid units may be dihydrogenated. Species of the *Microbacteriaceae* are characterized by a predominance of menaquinones with 9–14 unsaturated isoprenoid units in their side chains. The majority of families are characterized by the peptidoglycan type A with the characteristic diamino acids lysine, ornithine, or *meso*-diaminopimelic acid. However, the family *Microbacteriaceae* exhibits peptidoglycan type B with the characteristic diamino acids lysine, ornithine, or diamino butyric acid but never diaminopimelic acid. Most of the fatty acids of representatives of the order are branched acids of the iso- and anteiso-type. Moderate amounts of straight chain fatty acids may be present as well, and *Janibacter* species exhibit a high proportion of unbranched acids (Kämpfer et al., 2006). Diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and unknown glycolipids are widely distributed among species of the order. Families of this order may be distinguished by a set of signature nucleotides in the 16S rRNA sequence (Table 70).

Family I. **Micrococcaceae** Pribham 1929, 361^{AL} emend. Stackebrandt, Rainey and Ward-Rainey 1997, 479

HANS-JÜRGEN BUSSE

Mi.cro.coc.ca.ce′a.e. N.L. masc. n. *Micrococcus* type genus of the family; suff. -*aceae* ending to denote a family; N.L. fem. pl. n. *Micrococcaceae* the *Micrococcus* family.

Representatives of the family are characterized by a pattern of 16S rRNA signatures consisting of certain nucleotides at positions 293:304 (G–U), 610 (G), 598:640 (U–U), 615:625 (G–C), 839:847 (A–U), 859 (U), 1025:1036 (C–G), 1026:1035 (C–G), 1265:1270 (U–G), and 1278 (U). All species of the family have a type **A** peptidoglycan with the diamino acid **L-lysine**. Respiratory quinones are **menaquinones** predominantly with **7–10 isoprenoid units** in the side chain, which are either completely **unsaturated, dihydrogenated, or a combination of both.** Polar lipid profiles usually contain **phosphatidyglycerol, diphosphatidylglycerol, phosphatidylinositol, and unknown glycolipid(s).** Genera affiliated with this family are *Micrococcus*, *Acaricomes*, *Arthrobacter*, *Citricoccus*, *Kocuria*, *Nesterenkonia*, *Renibacterium*, *Rothia*, *Yaniella*, and *Zhihengliuella*.

Type genus: **Micrococcus** (Cohn 1872) emend. Stackebrandt, Koch, Gvozdiak and Schumann 1995, 691 emend. Wieser Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax and Busse 2002, 629.

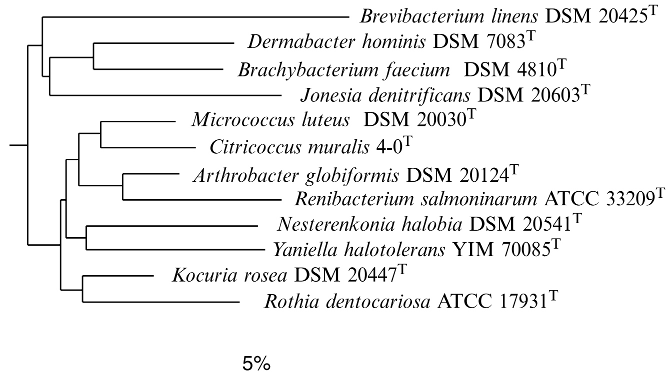

FIGURE 136. Neighbor joining tree (Felsenstein, 1993b) based on 16S rRNA gene sequences of some members of the family *Micrococcaceae* and some related genera, represented by their type species. Bootstrap values (>30%) of 500 resamplings (Felsenstein, 1985) are indicated at nodes. The scale represents 5 inferred nucleotide changes per 100 nucleotides.

Further descriptive information

The family *Micrococcaceae* proposed by Pribham (1929) was later reorganized and emended by Stackebrandt et al. (1997) exclusively based on signature nucleotides in the 16S rRNA gene sequences. At that time, in addition to the type genus *Micrococcus*, the genera *Arthrobacter* (Conn and Dimmick 1947) Koch et al. 1995, *Kocuria*, *Nesterenkonia* Stackebrandt et al. 1995, *Renibacterium* Sanders and Fryer 1980, *Rothia* Georg and Brown 1967, and *Stomatococcus* Bergan and Kocur 1982 were placed into this family. Recently, the single species of the latter genus, *Stomatococcus mucilaginosus*, was reclassified as *Rothia mucilaginosa* Collins et al. 2000. Subsequently, three additional genera were assigned to the family including *Citricoccus* Altenburger et al. 2002, *Acaricomes* Pukall et al. 2006, and *Zhihengliuella* Zhang et al. 2007; in the roadmap to the present volume, the genus *Yaniella* Li, Zhi and Euzéby 2008b has also been incorporated into the family *Micrococcaceae* (Figure 136). Genera of this family share the characteristics of the order *Micrococcales*. The polyamines of the representatives of the family examined thus far, including species of the genera *Micrococcus*, *Kocuria*, *Arthrobacter*, and *Citricoccus* (Altenburger et al., 1997, 2002; Gvozdiak et al., 1998; Hamana, 1994), are mainly spermidine, often with moderate amounts of spermine (exception: *Arthrobacter uratoxydans* exhibiting spermine predominantly).

Genus I. **Micrococcus** Cohn 1872, 151^{AL} emend. Stackebrandt, Koch, Gvozdiak, Schumann 1995, 682 emend. Wieser, Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax and Busse 2002, 635

HANS-JÜRGEN BUSSE

Mi.cro.coc′cus. Gr. adj. *mikros* small, little; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Micrococcus* small coccus.

Cells are spherical and nonmotile. Endospores are not formed. Gram-stain-positive. Aerobic. **Chemo-organotrophic**, metabolism is strictly respiratory. Catalase- and oxidase-positive. Mesophilic. Non halophilic. The **peptidoglycan contains L-lysine as the diagnostic diamino acid**. The **peptidoglycan type** is either **A2**, with the interpeptide bridge consisting of a stem peptide or **A4α** both with lysine as the diagnostic diamino acid. The **predominant menaquinones** are either **MK-8 and MK-8(H_2)** or **MK-8(H_2)** or **MK-7(H_2) and MK-8(H_2)**. The cytochromes are aa_3, b_{557}, b_{567}, d_{626}; cytochromes c_{550}, c_{551}, b_{563}, b_{564} and b_{567} may be present. Polar lipids are **phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol**, an unknown **glycolipid**, and an unknown ninhydrin-negative **phospholipid**. The cellular fatty acids are **iso- and anteiso-branched fatty acids**, with **$C_{15:0}$ anteiso and $C_{15:0}$ iso** predominating. The major aliphatic hydrocarbons (br-Δ-C) are C_{27} to C_{29}. Mycolic acids and teichonic acids are absent; teichuronic acids may be present. Mannosamine-uronic acid may be present as an amino sugar in the cell-wall polysaccharide. D-Arabinose, *p*-arbutin, D-cellobiose, D-galactose, D-melibiose, D-ribose, and salicin are not assimilated. Members of the genus share the *Micrococcaceae*-specific signature nucleotides at positions 293:304, 610, 598, 615:625, 1025:1036, 1026:1035,

1265:1270, and 1278 of the 16S rRNA gene sequence (*Escherichia coli* numbering) and lack the signature nucleotides at positions 640, 839:847, and 859 (Stackebrandt et al., 1997).

DNA G+C content (mol%): 69–76.

Type species: **Micrococcus luteus** (Schroeter) Cohn 1872, 153[AL] emend. Wieser Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax and Busse 2002, 635.

Further descriptive information

The genus *Micrococcus* is the type genus of the order *Micrococcales* Prévot 1940 and the family *Micrococcaceae* Pribram 1929. Former members of the genus including *Micrococcus varians*, *Micrococcus kristinae*, *Micrococcus roseus*, *Micrococcus agilis*, *Micrococcus sedentarius*, *Micrococcus nishinomiyanensis*, and *Micrococcus halobius* have been reclassified in other genera based on their distinct phylogenetic positions and differences in the quinone systems, interpeptide bridges of the peptidoglycans, and fatty acids (Koch et al., 1995; Stackebrandt et al., 1995). *Micrococcus varians*, *Micrococcus kristinae*, and *Micrococcus roseus* were reclassified as species of the genus *Kocuria*. *Micrococcus agilis* was transferred to the genus *Arthrobacter*. *Micrococcus sedentarius*, *Micrococcus nishinomiyanensis*, and *Micrococcus halobius* were proposed as species of the genera *Kytococcus*, *Dermacoccus*, and *Nesterenkonia*, respectively.

The genus now consists of six species, *Micrococcus luteus* (the type species of the genus), *Micrococcus lylae*, *Micrococcus antarcticus*, *Micrococcus endophyticus*, *Micrococcus yunnanensis*, and *Micrococcus flavus* (differential characteristics are shown in Table 71). The type strains of the species are separated from each other at 97.8–99.8% 16S rRNA gene sequence similarities. Some representatives of related genera such as *Citricoccus* and *Arthrobacter* show only slightly lower similarity values with the type strains of *Micrococcus* species indicating the limitations of 16S rRNA gene sequence similarities for genus affiliation within this group. Among reliably identified *Micrococcus luteus* strains, the isolate *Micrococcus luteus* strain 118 (accession no. AJ312751; Wieser et al., 2002) exhibits only 98.9% similarity with the type strain of *Micrococcus luteus* DSM 20030 (accession no. AJ536198) in the 16S rRNA gene sequence but 99.1% with the type strain of *Micrococcus yunnanensis*. Hence, 98.9% similarity is not sufficient to indicate species identity, at least for the species *Micrococcus luteus* and *Micrococcus yunnanensis*.

Species of the genus share the coccus shape and the inability to assimilate the carbon sources L-arabinose, cellobiose, D-melibiose, D-ribose, and salicin. The species are characterized by a quinone system with menaquinone MK-8(H_2) [large amounts of MK-8 and MK-7(H_2) may be present as well], a fatty acid profile predominated by $C_{15:0}$ anteiso and $C_{15:0}$ iso (<60%), and a lysine based peptidoglycan type A2 or A4α (Schleifer and Kandler, 1972). *Micrococcus luteus* is so far the only species with strains having different quinone systems, either MK-8 and MK-8(H_2) or MK-8(H_2) and different peptidoglycans, either A2 or A4α (Wieser et al., 2002).

Optimal growth temperature reflects the natural habitat of some *Micrococcus* species. *Micrococcus antarcticus* isolated from Antarctica grows best at 16.8°C; *Micrococcus flavus* isolated from activated sludge grows best at 31°C; and *Micrococcus luteus* and *Micrococcus lylae* both isolated from human and other mammal skin exhibit optimal growth at 37°C. Kloos and Musselwhite (1975) showed that *Micrococcus luteus* is the predominant organism isolated from skin of the head, legs, and arms whereas *Micrococcus lylae* is only occasionally isolated from skin but most frequently during the colder seasons. The association of *Micrococcus luteus* with humans is also indicated by the higher frequency of recovery from air-borne bacteria collected in the "Museo Correr" in Venice, Italy, during visiting hours (Camuffo et al., 1999; Wieser et al., 2002). *Micrococcus luteus* and more rarely *Micrococcus lylae*, can be also isolated from different foodstuffs. During the production of cassava fish among others, *Micrococcus luteus* can be isolated early in the fermentation process (Anihouvi et al., 2007). *Micrococcus luteus* has been isolated in moderate amounts from "androlla" (a Spanish dry-fermented sausage; García Fontán et al., 2007) and detected during ripening of Camembert cheese (Addis et al., 2001) and in goat cheese (Prado et al., 2001). Micrococci are the only Gram-stain-positive bacteria which can be isolated from ice-stored fish, and strains of *Micrococcus luteus* were shown to make up almost 20% of totally recovered strains from this source (Lakshmanan et al., 2002a).

Enrichment and isolation procedures

Micrococcus species do not exhibit special growth requirements. Common media containing yeast extract and peptone and a pH close to 7.0 are suitable for isolation. Specific isolation of *Micrococcus antarcticus* and *Micrococcus yunnanensis* may be done at 4°C. To suppress growth of staphylococci, the medium for isolation of *Micrococcus luteus* should be supplemented with 0.03% (w/v) furazolidone (Baker, 1984) and 10% (w/v) NaCl (Wieser et al., 2002) and incubated at 45°C.

Pathogenicity. There are only a few reports dealing with micrococci related to human infections. However, *Micrococcus luteus* in particular can be considered an opportunistic pathogen. Strains of this species were identified as causative agents of septic shock (Albertson et al., 1978), meningitis (Fosse et al., 1985), septic arthritis (Wharton et al., 1986), endocarditis (Dürst et al., 1991; Glupczynski et al., 1986; Seifert et al., 1995), infections associated with indwelling lines, continuous ambulatory peritoneal dialysis, or a ventriculo-peritoneal shunt (Magee et al., 1990), intracranial suppuration (Selladurai et al., 1993), bacteremia (Peces et al., 1997; von Eiff et al., 1996), chronic cutaneous infections in HIV-positive patients (Smith et al., 1999), and catheter infection (Oudiz et al., 2004).

Another threat to human health is the ability of *Micrococcus luteus* to produce cadaverine in food through the action of lysine decarboxylase (Lakshmanan et al., 2002b). Cadaverine itself has little toxicity but it potentiates the toxicity of histamine in food by inhibiting histamine-metabolizing enzymes such as diamine oxidase and histamine *N*-methyl-transferase (Taylor and Sumer, 1986).

Maintenance procedures

Micrococcus cultures may be lyophilized or stored as a glycerol culture at −80°C by common procedures used for many bacteria. Storage on agar slants at 4°C for several weeks can be recommended.

Differentiation of the genus *Micrococcus* from other genera

Micrococcus species may be distinguished from other genera of the family *Micrococcaceae* and its nearest phylogenetic neighbors, members of the genus *Citricoccus*, by cell-wall peptidoglycan type and menaquinone system (Table 72).

TABLE 71. Characteristics differentiating representatives of the genus *Micrococcus* from other related genera containing coccus-shaped species

Characteristic	*Micrococcus*[a]	*Citricoccus*[b]	*Dermacoccus*[c]	*Kocuria*[d]	*Kytococcus*[e]	*Nesterenkonia*[f]	*Rothia*[g]
Quinone system	MK-8, MK-8(H_2) or MK-8(H_2) or MK-7(H_2), MK-8(H_2)	MK-9(H_2)	MK-8(H_2)	MK-7(H_2) or MK-8(H_2) or MK-7(H_2), MK-8(H_2) or MK-8(H_2), MK-9(H_2), MK-7(H_2) or MK-8(H_2), MK-9(H_2)	MK-8, MK-7 or MK-8, MK-9, MK-10	MK-7 or MK-8 or MK-7, MK-8 or MK-8, MK-7, MK-9 or MK-8, MK-9	MK-7 or MK-7, MK-6(H_2)
Peptidoglycan interpeptide bridge	L-Lys–peptide subunit or L-Lys–D-Asp	Lys–Gly–Glu	L-Lys–L-$Ser_{1–2}$–(L-Ala)–D-Glu	L-Lys–L-$Ala_{3–4}$	L-Lys–Glu_2	L-Lys–Gly–D-Asp or L-Lys–L-Glu or L-Lys–Gly–L-Glu	L-Lys–L-Ala
Major fatty acids (>25%)	$C_{15:0}$ anteiso or $C_{15:0}$ anteiso and $C_{15:0}$ iso	$C_{15:0}$ anteiso or $C_{15:0}$ anteiso and $C_{17:0}$ anteiso	$C_{16:0}$ iso[h]	$C_{15:0}$ anteiso	$C_{17:0}$ anteiso or $C_{17:1}$ anteiso	$C_{16:0}$ iso or $C_{15:0}$ anteiso or $C_{16:0}$, $C_{15:0}$ anteiso or $C_{17:0}$ anteiso, $C_{15:0}$ anteiso	$C_{15:0}$ anteiso
Acid produced from carbohydrates	–	–	–	+	– or weakly +	+[i]	+
DNA G+C content (mol%)	66.4–75.5	63.8–68.0	65.2–69.1	60.0–75.3	68–69	68.0	54.5–57.8

[a]Data from Kocur et al. (1972), Stackebrandt et al. (1995), Wieser et al. (2002), Liu et al. (2000), and Liu et al. (2007).

[b]Data from Altenburger et al. (2002) and Li et al. (2005b).

[c]Data from Stackebrandt et al. (1995) and Pathom-aree et al. (2006b, 2006c).

List of species of the genus *Micrococcus*

1. **Micrococcus luteus** (Schroeter) Cohn 1872, 153[AL] (synonym: "*Bacteridium luteum*" Schroeter 1872, 126); emend. Wieser et al., 2002, 635

lu′te.us. L. masc. adj. *luteus* golden yellow.

The species shares the properties given in the genus description. Additional characteristics are: cells occur in tetrads and in irregular clusters of tetrads and form smooth, convex colonies with regular edge. Colonies forming cubical packets usually have a granular surface and a matt appearance. Colonies are yellow, yellowish green, or orange pigmented. Some strains form a violet pigment which diffuses into the medium. The optimal growth temperature range is 25–37°C. Growth or weak growth is observed at 45°C, at pH 10.0, and in the presence of 10% NaCl; no growth is observed in the presence of 15% NaCl. Urease-variable. D-Glucose, sucrose, and D-mannose are assimilated. D-Fructose, *N*-acetyl-D-glucosamine, L-rhamnose, gluconate, *cis*-aconitate, *trans*-aconitate, adipate, azelate, itaconate, mesaconate, suberate, β-alanine, L-ornithine, L-tryptophan, L-leucine, 3-hydroxybenzoate, and 4-hydroxybenzoate are not assimilated. *p*-Nitrophenyl (pNP) α-glucopyranoside, and L-alanine *p*-nitroanilide (pNA) are hydrolyzed. pNP D-Galactopyranoside, pNP D-glucuronide, pNP D-glycopyranoside, bis-pNP phosphate, pNP phenylphosphate, pNP phosphorylcholine, 2-deoxythymidine-5′-pNP phosphate, and L-glutamate-3-carboxy pNA are not hydrolyzed. The peptidoglycan variation is either A2 or A4α. The predominant menaquinones are either MK-8 and MK-8(H_2) or MK-8(H_2) alone. MK-7 or MK-7(H_2) and MK-9(H_2) and MK-6(H_2) occur in minor amounts.

Source: mammalian skin.

DNA G+C content (mol%): 70–75.5 (T_m, Bd, HPLC) (Kocur et al., 1972; Wieser et al., 2002); 73 (genome sequence of the type) (Young et al., 2010).

Type strain: ATCC 4698, CCM 169, CCUG 5858, CIP A270, DSM 20030, HAMBI 26, HAMBI 1399, IEGM 391, NBRC3333, JCM 1464, LMG 4050, NCCB 78001, NCTC 2665, NRRL B-287, VKM B-1314.

Sequence accession no. (16S rRNA gene): AJ536198.
Sequence accession no. (complete genome): CP001628 (2.5 MB)
Sequence accession no. (recA gene): AF214783.
Additional remarks: based on substantial chemotaxonomic differences, Wieser et al. (2002) proposed dissection of the species *Micrococcus luteus* into three biovars (see below).

Biovar I. In addition to the properties given in the species description, members of this biovar have the following characteristics. No growth is observed at pH 6.0. Urease-positive. Maltitol, L-aspartate, and propionate are assimilated. D-Maltose, D-trehalose, D-xylose, adonitol, iso-inositol, D-mannitol, D-sorbitol, putrescine, acetate, 4-aminobutyrate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, DL-lactate, L-malate, oxoglutarate, pyruvate, L-alanine, L-histidine, L-phenylalanine, L-proline, L-serine, and phenylacetate are not assimilated. L-Proline pNA and Tween 20 are hydrolyzed. Casein and Tween 80 are not hydrolyzed. The peptidoglycan type is A2. The major menaquinones are MK-8 and MK-8(H_2). The reference strain for this biovar is the designated type strain for the species, *Micrococcus luteus* DSM 20030.

Biovar II. In addition to the properties given in the species description, members of this biovar have the following characteristics. Colonies are creamy yellow in color, circular, entire, and convex. Growth at pH 6.0 is variable. Urease-variable. D-Maltose, D-trehalose, acetate, propionate, DL-3-hydroxybutyrate, DL-lactate, pyruvate, L-histidine, L-phenylalanine, L-serine, and phenylacetate are assimilated. Oxoglutarate is not assimilated. Assimilation of D-xylose, adonitol, iso-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, 4-aminobutyrate, citrate, fumarate, glutarate, L-malate, L-alanine, L-aspartate, and L-proline is variable. Casein and L-proline pNA are hydrolyzed. Hydrolysis of Tween 20 and Tween 80 is variable. The major menaquinone is MK-8(H_2). The peptidoglycan type is A2.
Source: a medieval wall painting and from indoor air.
DNA G+C content (mol%): 71 (HPLC).
Reference strain: D7, DSM 14234, CCM 4959.
Sequence accession no. (16S rRNA gene): AJ409095

Biovar III. In addition to the properties given in the species description, the single member of this biovar has the following characteristics. Colonies are creamy yellow in color, circular, entire, and convex. No growth is observed at pH 6.0. Urease-positive. D-Maltose, D-trehalose, 4-aminobutyrate, fumarate, DL-3-hydroxybutyrate, DL-lactate, oxoglutarate, pyruvate, L-histidine, and L-proline are assimilated. D-Xylose, adonitol, iso-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, acetate, propionate, citrate, glutarate, L-malate, L-alanine, L-aspartate, L-phenylalanine, L-serine, and phenylacetate are not assimilated. Tween 20 and casein are hydrolyzed. L-Proline pNA and Tween 80 are not hydrolyzed. The main menaquinone is MK-8(H_2). The peptidoglycan variation is A4α. Strain Ballarat was isolated from an activated-sludge plant in Ballarat, Victoria, Australia.
DNA G+C content (mol%): 70 (HPLC).
Reference strain: strain Ballarat, DSM 14235, CCM 4960.
Sequence accession no. (16S rRNA gene): AJ409096.

2. **Micrococcus antarcticus** Liu, Xu, Ma and Zhou 2000, 718[VP]

an.tarc′ti.cus. L. masc. adj. *antarcticus* southern, referring to the Antarctic habitat of the bacterium.

Cells are spherical, have a diameter of 0.5 µm and are nonmotile. Endospores are not formed. Gram-stain-positive, aerobic. Colonies are yellow, mucoid, and fluffy with entire margins. Optimal growth occurs at 15–17°C. Catalase- and oxidase-positive. Positive for indole formation, Voges–Proskauer, methyl red, and nitrate reduction. Starch, Tween 20, Tween 40, and Tween 80 are hydrolyzed. The following carbon sources are utilized: arabitol, fructose, fucose, gluconic acid, mannitol, rhamnose, turanose, xylitol, hydroxybutyric acid, L-lactic acid, L-malic acid, D-malic acid, methyl pyruvate, mono-methyl succinate, succinamic acid, succinic acid, *N*-acetyl L-glutamic acid, alaninamide, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-pyroglutamic acid, L-serine, glycerol, adenosine, inosine, thymidine, and uridine. The following biochemical tests are negative: urease, acetoin, and arginine dihydrolase. Gelatin and esculin are not hydrolyzed. Acid production from carbohydrates is negative. There is no utilization of the following carbon sources: dextrin, glycogen, inulin, mannan, amygdalin, L-arabinose, arbutin, cellobiose, D-galactose, D-galacturonic acid, gentiobiose, D-glucose, *myo*-inositol, D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melezitose, D-melibiose, 3-methyl glucose, palatinose, psicose, raffinose, D-ribose, salicin, sorbitol, stachyose, sucrose, D-tagatose, D-trehalose, D-xylose, acetic acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, propionic acid, pyruvic acid, and 2,3-butanediol. Susceptible to lysozyme, penicillin, tetracycline, erythromycin, novobiocin, streptomycin, methicillin, chloramphenicol, polymyxin, and neomycin. The diagnostic peptidoglycan diamino acid is L-lysine. The predominant menaquinones are MK-8 and MK-8(H_2). The amino sugar in the cell-wall polysaccharide is mannosamine. Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso.
Source: Chinese Great-Wall station in Antarctica.
DNA G+C content (mol%): 66.4 (T_m).
Type strain: strain T2, AS 1.2372, JCM 11467.
Sequence accession no. (16S rRNA gene): AJ005932.

3. **Micrococcus endophyticus** Chen, Zhao, Park, Zhang, Xu, Lee, Kim and Li 2009, 1073[VP]

en.do.phy′ti.cus. Gr. pref. *endo-* within; Gr. neut. n. *phyton* plant; L. masc. suff. *-icus* suffix used with the sense of pertaining to; N.L. masc. adj. *endophyticus* within plant, pertaining to the original isolation from plant tissues.

Cells are spherical, Gram-stain-positive, aerobic, non-endospore-forming, coccoid and 0.5–0.7 µm in diameter. Motility is not observed. Colonies on TSA are yellow, slimy, smooth, and circular with entire margins. No pigment is produced. The temperature, pH, and NaCl ranges for growth are 15–37°C, pH 6–9, and 0–10% (w/v). Optimal growth occurs at 28°C and at around pH 7.0–8.0. Catalase-positive and oxidase-positive. Gelatin but not starch and Tween 80 is hydrolyzed. The Voges–Proskauer reaction is negative and the reduction of nitrate is positive. Positive for acid production from *N*-acetylglucosamine, esculin, D-arabinose, L-arabinose, arbutin, cellobiose, fructose, galactose, D-lyxose, methyl α-D-glucoside, raffinose, ribose, sorbitol, trehalose, mannose, maltose, sucrose, D-glucose and 5-ketogluconate, but negative for acid production from adonitol, dulcitol, erythritol, D-fucose, β-gentiobiose, gluconate, glycerol, glycogen, inositol, inulin, lactose, mannitol, melezitose, melibiose, methyl β-D-mannoside, rhamnose, salicin, sorbose, starch,

D-tagatose, L-xylose, D-xylose, methyl β-D-xyloside, amygdalin, D-arabitol, L-arabitol, L-fucose, 2-ketogluconate, and xylitol. The cell-wall peptidoglycan of the type strain contains lysine, glutamic acid, alanine, and glycine. The phospholipids consist of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and an unknown ninhydrin-negative phospholipid. The predominant menaquinones are MK-8(H_2) (63.6%) and MK-7(H_2) (21.1%). The major cellular fatty acids are $C_{15:0}$ iso and $C_{15:0}$ anteiso.

Source: surface-sterilized roots of the plant *Aquilaria sinensis*, collected in the tropical rainforest of Yunnan Province in south-west China.

DNA G+C content (mol%): 72.9 (T_m).

Type strain: YIM 56238, DSM 17945, KCTC 19156.

Sequence accession no. (16S rRNA gene): EU005372.

4. **Micrococcus flavus** Liu, Wang, Jiang and Liu 2007, 66[VP]

fla'vus. L. masc. adj. *flavus* yellow, pertaining to the yellow color of the colonies.

Cells are spherical, 0.7–1.0 µm in diameter and nonmotile. Gram-stain-positive, aerobic, and heterotrophic. Colonies are yellow, smooth, and circular with entire margins. Optimal growth occurs at 30.5–31.5°C and pH 6–6.2. Catalase- and oxidase-positive. Starch is hydrolyzed. Negative for the Voges–Proskauer reaction, lipase, reduction of nitrate, and utilization of citric acid. Gelatin is not hydrolyzed. No acid production from carbohydrates. Glycerol, trehalose, and dextrin are used as carbon sources, but D-arabinose, fructose, mannitose, rhamnose, melibiose, xylitol, malic acid, L-glutamic acid, L-lactic acid, nitrilosides, L-arabinose, cellobiose, D-lactose, D-glucose, inositol, maltose, D-mannose, D-melibiose, raffinose, D-ribose, salicin, and sorbitol are not. The predominant menaquinones are MK-8(H_2) and MK-7(H_2). The major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. The peptidoglycan is composed of lysine, glutamic acid, alanine, glycine, and aspartic acid suggesting type A4α.

Source: activated sludge in a bioreactor.

DNA G+C content (mol%): 71.4 (T_m).

Type strain: LW4, CGMCC 1.5361, JCM 14000, DSM 19079, CIP 109517.

Sequence accession no. (16S rRNA gene): DQ491453.

5. **Micrococcus lylae** (Kloos, Tornabene and Schleifer 1974) emend. Wieser, Denner, Kämpfer, Schumann, Tindall, Steiner, Vybiral, Lubitz, Maszenan, Patel, Seviour, Radax and Busse 2002; 636[VP]

ly'la.e. N.L. gen. fem. n. *lylae* of Lyla; named for Lyla Kloos, by whom this organism was originally isolated.

The species shares the properties given in the genus description. Additional characteristics are: D-glucose, sucrose, D-fructose, D-maltose, D-trehalose, maltitol, acetate, citrate, fumarate, DL-3-hydroxybutyrate, DL-lactate, pyruvate, L-aspartate, L-histidine, L-leucine, 3-hydroxybenzoate, and 4-hydroxybenzoate are assimilated. L-Mannose, L-xylose, adonitol, iso-inositol, D-mannitol, D-sorbitol, *N*-acetyl-D-glucosamine, L-rhamnose, gluconate, *cis*-aconitate, *trans*-aconitate, adipate, azelate, itaconate, mesaconate, suberate, putrescine, propionate, glutarate, L-malate, oxoglutarate, 4-aminobutyrate, L-ornithine, L-tryptophan, β-alanine, L-alanine, L-phenylalanine, L-proline, L-serine, and phenylacetate are not assimilated. pNP α-Glucopyranoside, L-alanine pNA, L-proline pNA, Tween 20 and Tween 80 are hydrolyzed. pNP D-Galactopyranoside, pNP D-glucuronide, pNP D-glycopyranoside, bis-pNP phosphate, pNP phenylphosphate, pNP phosphorylcholine, 2-deoxythymidine-5′-pNP phosphate, L-glutamate-3-carboxy pNA, and casein are not hydrolyzed. The main menaquinone is MK-8(H_2). The peptidoglycan type is A4α. Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso.

Source: mammalian skin.

DNA G+C content (mol%): 68.6 ± 0.8 (T_m) (Kloos et al., 1974).

Type strain: ATCC 27566, CCM 2693, CCUG 33027, CIP 81.70, DSM 20315, IEGM 392, NBRC15355, JCM 11572, LMG 14218, NCTC 11037, VKM B-1815.

Sequence accession no. (16S rRNA gene): X80750.

Sequence accession no. (recA gene): AF214778.

6. **Micrococcus yunnanensis** Zhao, Li, Qin, Zhang, Zhu, Jiang, Xu and Li 2009, 2386[VP]

yun.na.nen'sis. N.L. masc. adj. *yunnanensis* of or pertaining to Yunnan, a province of south-west China.

Cells are Gram-stain-positive, aerobic, non-endospore-forming cocci (0.8–1 µm in diameter). Motility is not observed. Colonies on TSA are yellow, smooth, and circular with entire margins. No pigment is produced. Temperature, pH, and NaCl tolerance ranges for growth are 4–45°C, pH 6–8, and 0–15 % (w/v), respectively. Optimal growth occurs at 28°C and about pH 7.0–8.0. Catalase-positive and oxidase-negative. Gelatin and starch are not hydrolyzed. Negative for methyl red, Voges–Proskauer reaction, urease, and the reduction of nitrate. Acid is produced from melibiose and trehalose but not from adonitol, amylum, D-arabinose, L-arabinose, arbutin, cellobiose, dulcitol, erythritol, esculin, fructose, D-fucose, galactose, β-gentiobiose, glycogen, gluconate, inositol, inulin, lactose, D-lyxose, mannitol, melezitose, methyl α-D-mannoside, methyl α-D-glucoside, *N*-acetylglucosamine, raffinose, rhamnose, ribose, salicin, sorbitol, sorbose, D-tagatose, and D-xylose. The cell-wall peptidoglycan contains lysine, glutamic acid, alanine, glycine, and aspartic acid. The phospholipids consist of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and an unknown ninhydrin-negative phospholipid. The predominant menaquinones are MK-8(H_2) (67%) and MK-7(H_2) (26%). Major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso.

Source: surface-sterilized roots of *Polyspora axillaris*, collected in Yunnan Province, south-west China.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: YIM 65004, CCTCC AA 208060, DSM 21948.

Sequence accession no. (16S rRNA gene): FJ214355.

Genus II. **Acaricomes** Pukall, Schumann, Schütte, Gols and Dicke 2006, 465^{VP}

Hans-Jürgen Busse

A.ca.ri.co′mes. N.L. masc. pl. n. *acari* the mites; L. masc. n. *comes* companion; N.L. masc. n. *Acaricomes* companion of mites.

Gram-stain-positive, aerobic, non-endospore-forming rods. A rod–coccus life cycle is absent. Mesophilic. The pH optimum for growth is pH 6.0–8.0. Catalase-positive, oxidase-negative. The **peptidoglycan type** is **A3α** L-Lys–L-Ala$_3$. The **predominant menaquinone** is dihydrogenated **menaquinone MK-10(H$_2$)**; in addition, methylmenaquinone **MMK-10(H$_2$)** is detectable. The **main fatty acids** determined are **C$_{15:0}$ anteiso and C$_{17:0}$ anteiso**. The major **polar lipids** are **phosphatidylglycerol, diphosphatidylglycerol**, and **phosphatidylinositol**.

DNA G+C content (mol%): 57.7 (HPLC).

Type species: **Acaricomes phytoseiuli** Pukall, Schumann, Schütte, Gols and Dicke 2006, 465^{VP}.

Further descriptive information

Acaricomes phytoseiuli has been isolated from the diseased predator mite *Phytoseiulus persimilis* Athias-Henriot (Pukall et al., 2006). Phylogenetically, the species is placed in the vicinity of the genera *Renibacterium* and *Arthrobacter* sharing 94–95% 16S rRNA gene sequence similarities with certain species including *Renibacterium salmoninarum*, *Arthrobacter globiformis*, *Arthrobacter woluwensis*, and *Arthrobacter russicus*. *Acaricomes phytoseiuli* exhibits peptidoglycan type A3α (L-Lys–L-Ala$_{2–3}$), a fatty acid profile consisting predominantly of anteiso-branched acids (C$_{15:0}$ anteiso and C$_{17:0}$ anteiso), a polar lipid profile with the components phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol and a quinone system with the major compound MK-10(H$_2$). While this peptidoglycan type, fatty acid profile, and polar lipid patterns are common among the family *Micrococcaceae*, the quinone system is rather unusual supporting the placement of this species in a separate genus.

Enrichment and isolation procedures

Acaricomes phytoseiuli may be isolated from its host (the predator mite *Phytoseiulus persimilis*) after surface-sterilization on Luria Bertoni Agar and incubation for 1 week at 25°C under aerobic conditions (Pukall et al., 2006).

Pathogenicity. *Acaricomes phytoseiuli* is assumed to be the causative agent of the "non-responding syndrome" in *Phytoseiulus persimilis* (Bjørnson and Schütte, 2003; Dicke et al., 2000; Schütte et al., 1998) but no information is available suggesting its pathogenic potential for humans.

Maintenance procedures

No information is available concerning maintenance of *Acaricomes phytoseiuli*.

Differentiation of the genus *Acaricomes* from other genera

So far, the genus is only represented by a single strain of a single species. Hence, it is not very clear which of the traits characterizing *Acaricomes phytoseiuli* in fact is sufficiently conserved to be also shared by other species of the genus. However, there is some probability that chemotaxonomic traits such as quinone system, polar lipids, peptidoglycan composition, and fatty acids fulfill the requirement of genus-specificity (Table 105). The quinone system with menaquinone MK-10(H$_2$) and presence of methylmenaquinone MMK-10(H$_2$) is unique among species of related genera such as *Arthrobacter*, *Micrococcus*, *Citricoccus*, and *Renibacterium*. The interpeptide chain of the peptidoglycan consisting of L-Lys–L-Ala$_3$ distinguishes *Acaricomes phytoseiuli* from the majority of related species. Only three *Arthrobacter* species, *Arthrobacter globiformis*, *Arthrobacter ramosus*. and *Arthrobacter methylotrophus* as well as *Kocuria* species exhibit the same peptidoglycan type and most similar types were reported for *Arthrobacter crystallopoietes*, *Rothia* species (Lys–Ala), *Arthrobacter pascens*, *Arthrobacter russicus*, and *Arthrobacter stackebrandtii* (Lys–Ala$_2$) (Borodina et al., 2002b; Chou et al., 2008; Collins et al., 2000; Fan et al., 2002; Kim et al., 2004; Koch et al., 1995; Kovács et al., 1999; Li et al., 2006; Mayilraj et al., 2006; Reddy et al., 2003; Stackebrandt et al., 1995; Tvrzová et al., 2005a; Zhou et al., 2008a).

List of species of the genus *Acaricomes*

1. **Acaricomes phytoseiuli** Pukall, Schumann, Schütte, Gols and Dicke 2006, 465^{VP}

phy.to.sei′u.li. N.L. gen. masc. n. *phytoseiuli* of *Phytoseiulus* the nomenclatural genus name of the host mite.

The characteristics are as described for the genus with the following additional features. Cells are 0.5–0.8 × 1–1.5 μm in size. Colonies on TSA are circular, convex, 1–2 mm in diameter, and colored yellowish. Growth occurs at 15–30°C with an optimum of 25°C. Grows at pH 6.0–9.5. Utilizes dextrin, α-D-glucose, α-D-fructose, maltose, maltotriose, D-mannose, sucrose, turanose, L-glutamic acid, and glucose 1-phosphate. Utilization of Tween 80, palatinose, L-pyroglutamic acid, and glucose 6-phosphate is weak. The following substrates are not utilized: α- and β-cyclodextrin, glycogen, inulin, mannan, Tween 40, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, L-arabinose, D-arabitol, arbutin, D-cellobiose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, D-gluconic acid, *myo*-inositol, α-D-lactose, lactulose, D-mannitol, D-melezitose, D-melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl glucose, methyl α-glucoside, methyl β-D-glucoside, methyl α-D-mannoside, D-psicose, D-raffinose, L-rhamnose, D-ribose, salicin, sedoheptulosan, D-sorbitol, stachyose, D-tagatose, D-trehalose, xylitol, D-xylose, acetic acid, α-, β-, and γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketovaleric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, methylpyruvate, monomethyl succinate, propionic acid, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, D-alanine, L-alanyl glycine, glycyl L-glutamic acid, L-serine, putrescine, 2,3-butanediol, glycerol, adenosine, 2′-deoxyadenosine, inosine, thymidine, uridine, adenosine 5′-monophosphate, thymidine 5′-monophosphate, uridine

5′-monophosphate, fructose 6-phosphate, and DL-α-glycerol phosphate. Cell-wall sugars are galactose and glucose. Cellular fatty acid profile consists mainly of the branched fatty acids $C_{15:0}$ anteiso (53.6%) and $C_{17:0}$ anteiso (31.9%). $C_{16:0}$ iso (6.3%), $C_{16:0}$ (3.6%), and $C_{15:0}$ iso (1.7%). The quinone system is composed of the major compound menaquinone MK-10(H_2) and minor amounts of MK-11(H_2), MK-9(H_2), and MK-8(H_2). Methylmenaquinone is present as well.

Source: the predatory mite *Phytoseiulus persimilis.*

DNA G+C content (mol%): 57.7 (HPLC).

Type strain: CSC, DSM 14247, CCUG 49701, JCM 14300.

Sequence accession no. (16S rRNA gene): AJ812213.

Genus III. **Arthrobacter** Conn and Dimmick 1947, 301[AL] emend. Koch, Schumann and Stackbrandt 1995, 838

Hans-Jürgen Busse, Monika Wieser and Sandra Buczolits

Ar.thro.bac′ter. Gr. n. *arthron* a joint; N.L. masc. n. *bacter* a rod; N.L. masc. n. *Arthrobacter* a jointed rod.

The majority of species exhibit a marked rod–coccus growth cycle when grown in complex media; stationary-phase cultures (generally after 2–7 d) are composed entirely or largely of coccoid cells that are 0.6–1.0 µm in diameter; some species are showing only spherical cells throughout the growth cycle. **Fatty acid**s are predominantly iso- and anteiso-branched with **$C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso predominating**. Few species exhibit significant amounts of $C_{16:0}$. **Quinone system** is composed of **completely unsaturated or mono-saturated menaquinones with chain lengths of eight to ten isoprenoic units**. The **cell-wall peptidoglycan contains the diagnostic diamino acid lysine** with several variations in the interpeptide bridge conforming to **peptidoglycan type A3α or A4α**.

DNA G+C content (mol%): 55–72.

Type species: **Arthrobacter globiformis** (Conn 1928) Conn and Dimmick 1947, 301[AL].

Further descriptive information

The genus name *Arthrobacter* was proposed by Conn and Dimmick (1947), reviving the old name which had been proposed by Fischer (1895). This name was a *nomen nudum* (naked name) because no species was named, and subsequently the name had been abandoned even by Fischer. Conn and Dimmick (1947) classified three species in the genus *Arthrobacter*, the type species of the genus *Arthrobacter globiforme*, *Arthrobacter helvolum*, and *Arthrobacter tumescens*. Skerman et al. (1980) then listed *Arthrobacter globiforme* as *Arthrobacter globiformis*, and since then this name has been in use. Later, two species of the genus were reclassified in new genera. *Arthrobacter tumescens* first was classified in the genus *Pimelobacter* as *Pimelobacter tumescens* (Suzuki and Komagata, 1983) and later as the type species of the genus *Terrabacter*, *Terrabacter tumescens* (Collins et al., 1989). *Arthrobacter helvolum* was described as the type species of the genus *Pseudoclavibacter* as *Pseudoclavibacter helvolum* (Manaia et al., 2004).

Arthrobacters have been recovered from a huge variety of environments, including soils, sea water, fresh water, human skin, oil, brine, tobacco leaves, air, sewage and activated sludge, mural paintings, clinical specimens, and a cyanobacterial mat. van Waasbergen et al. (2000) even detected *Arthrobacter* strains in terrestrial subsurface sediments at depths between 170 and 220 m.

In the previous edition of *Bergey's Manual of Systematic Bacteriology*, Keddie et al. (1986) subdivided the genus *Arthrobacter* into two groups, the *Arthrobacter globiformis/Arthrobacter citreus* group and the *Arthrobacter nicotianae* group. Common characteristics of the *Arthrobacter globiformis/Arthrobacter citreus* group were the presence of the menaquinone MK-9(H_2) system and peptidoglycan type A3α, with the characteristic diamino acid L-lysine and an interpeptide chain consisting of monocarboxylic L-amino acids, glycine, or both (Schleifer and Kandler, 1972). Characteristics of the *Arthrobacter nicotianae* group were menaquinones with completely unsaturated isoprenoic side chains (MK-8 or MK-9) and peptidoglycan type A4α, with L-lysine and an interpeptide bridge containing a dicarboxylic amino acid. Species assigned to the *Arthrobacter globiformis/Arthrobacter citreus* group were *Arthrobacter globiformis*, *Arthrobacter pascens*, *Arthrobacter oxydans*, *Arthrobacter histidinolovorans*, *Arthrobacter ureafaciens*, *Arthrobacter ramosus*, *Arthrobacter ilicis*, *Arthrobacter aurescens*, *Arthrobacter citreus*, *Arthrobacter crystallopoietes*, and *Arthrobacter atrocyaneus* (Kuhn and Starr, 1960; since reclassified as *Sinomonas atrocyanea* Zhou et al., 2009). Species assigned to the *Arthrobacter nicotianae* group were *Arthrobacter nicotianae*, *Arthrobacter protophormiae*, *Arthrobacter uratoxydans*, and *Arthrobacter sulfureus.* Due to the absence of chemotaxonomic data, several other species were treated as *species incertae sedis*, including *Arthrobacter mysorens* (phylogenetically this species is related to the *Arthrobacter nicotianae* group; Figure 137); *Arthrobacter picolinophilus* [according to Koch et al. (1995) this species is a later heterotypic synonym of *Rhodococcus erythropolis*], *Arthrobacter radiotolerans* [reclassified as *Rubrobacter radiotolerans* (Suzuki et al., 1988)]; and *Arthrobacter siderocapsulatus* [according to Chun et al. (2001), this species is a later heterotypic synonym of *Pseudomonas putida*]. Other species showing *meso*- or LL-diaminopimelic acid as the characteristic diamino acid in the peptidoglycan were listed in two addenda: *Arthrobacter duodecanis* [reclassified as *Tetrasphaera duodecanis* (Ishikawa and Yokota, 2006)]; *Arthrobacter variabilis* [reclassified as *Corynebacterium variabilis* (Collins, 1987) and then renamed *Corynebacterium variabile* (Euzéby, 1998)]; *Arthrobacter viscosus* (the type of this species shares 96.9–99.6% similarity with species of the genus *Rhizobium* and hence reclassification as a species of *Rhizobium* is desirable); *Arthrobacter simplex* [reclassified as *Pimelobacter simplex* (Suzuki and Komagata, 1983)]; and *Arthrobacter tumescens* [reclassified as *Terrabacter tumescens* (Collins et al., 1989)].

Based on the amino acid composition of the peptidoglycan interpeptide chain, another grouping of *Arthrobacter* species was proposed by Komagata and Suzuki (1987) which dissected *Arthrobacter* species into seven groups designated Komagata/Suzuki groups I–VII (Table 73).

At present, the genus *Arthrobacter* consists of 64 recognized species. Based upon the EzTaxon server (Chun et al., 2007), with the exception of *Arthrobacter viscosus*, these *Arthrobacter* species

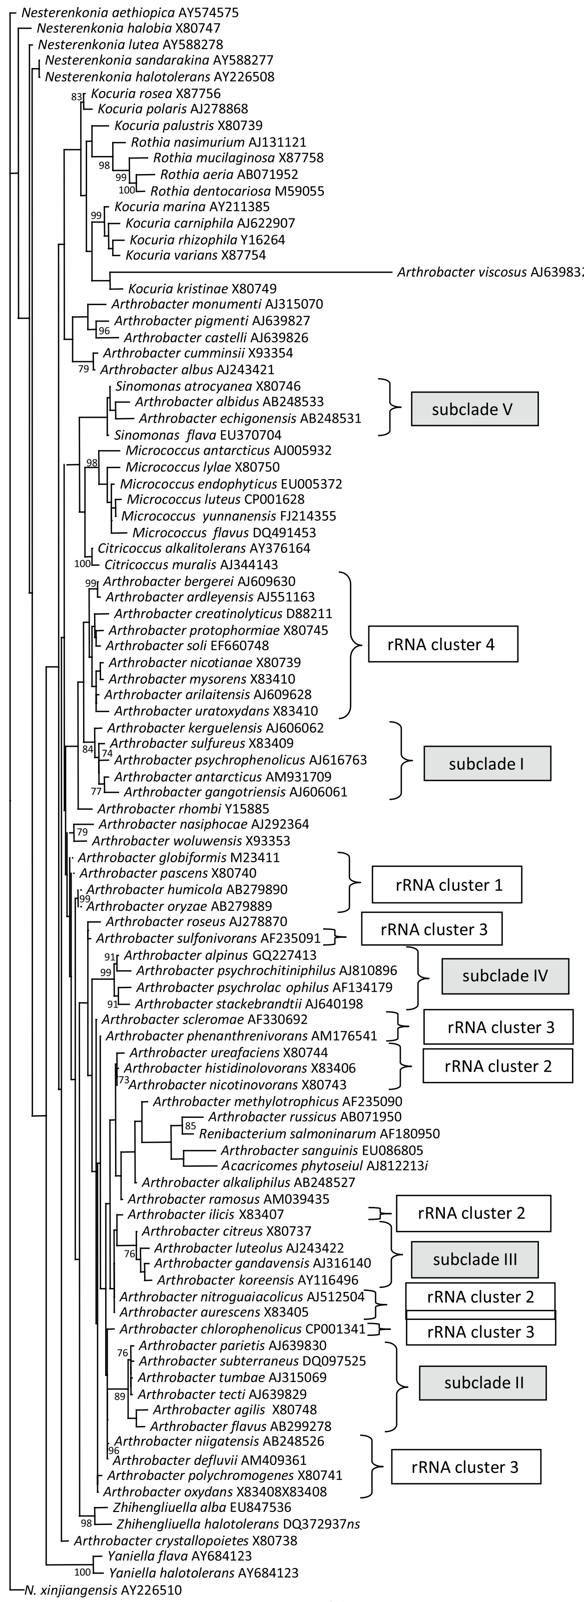

FIGURE 137. Maximum likelihood tree as implemented in the PHYLIP program (Felsenstein, 2009) based on 16S rRNA gene sequences of all recognized *Arthrobacter* species. Sequences were aligned using CLUSTAL_X (Thompson et al., 1997) and manually edited to remove gaps and ambiguous nucleotides in BIOEDIT (Hall, 1999). Bootstrap values of 70% and higher are shown at the nodes. Percentages are based on 100 resamplings. Bar = 10% sequence divergence.

TABLE 73. Classification of *Arthrobacter* species based on the composition of the interpeptide bridge of the peptidoglycan (Komagata and Suzuki, 1987)[a]

Komagata/ Suzuki group	Amino acid composition of the interpeptide bridge	Species
I	Lys–Ser–Thr–Ala	*A. oxydans*, *A. polychromogenes*
II	Lys–Ala–Thr–Ala	*A. aurescens*, *A. histidinolovorans*, *A. ilicis*, *A. nicotinovorans*, *A. ureafaciens*
III	Lys–$Ala_{1–4}$	*A. crystallopoietes*, *A. globiformis*, *A. pascens*, *A. ramosus*
IV	Lys–Ser–$Ala_{2–3}$	*Sinomonas atrocyanea* (formerly *A. atrocyaneus*)
V	Lys–Thr–Ala_2	*A. citreus*
VI	Lys–Ala–Glu	*A. nicotianae*, *A. creatinolyticus*, *A. uratoxydans*, *A. protophormiae*
VII	Lys–Glu	*A. sulfureus*

[a]Abbreviations: Lys, lysine; Ser, serine; Thr, threonine; Ala, alanine; Glu, glutamic acid.

share 16S rRNA gene sequence similarities of 94.4–99.3% with the type strain of the genus, *Arthrobacter globiformis*. Several species of related genera such as *Acaricomes*, *Brachybacterium*, *Citricoccus*, *Kocuria*, *Micrococcus*, *Nesterenkonia*, *Rothia*, *Sinomonas*, and *Zhihengliuella* also possess sequence similarities with *Arthrobacter globiformis* within this range. These observations indicate the heterogeneity of the genus *Arthrobacter*. Hence, identification of novel strains at the genus level only based on 16S rRNA gene sequence similarities are ambiguous if a high degree of similarity is not found with *Arthrobacter globiformis*. Also phylogenetic examinations indicate that *Arthrobacter* is a polyphyletic genus. Several *Micrococcaceae* genera, such as *Micrococcus*, *Citricoccus*, *Sinomonas*, *Acaricomes*, and *Renibacterium*, are included in the clade comprising all *Arthrobacter* species and separate the genus into several subclades (Figure 137). However, the majority of branching points in the phylogenetic tree calculated applying the maximum-likelihood (Figure 137) or neighbor-joining algorithms (not shown) are not supported by significant bootstrap values (>75%), indicating that the phylogenetic relationships among numerous *Arthrobacter* species remain ambiguous at this time.

Species of the *Arthrobacter globiformis*/*Arthrobacter citreus* group (Keddie et al., 1986) are distributed throughout the phylogenetic tree. Although not supported by significant bootstrap values, in many trees *Arthrobacter globiformis* and *Arthrobacter pascens* appear on a common branch, and *Arthrobacter ureafaciens* and *Arthrobacter histidinolovorans* appear on another (Figure 137). The remaining species of the *Arthrobacter globiformis*/*Arthrobacter citreus* group are distributed throughout phylogenetic trees and do not appear to be closely related to each other. For this reason, this group is probably artificial, and it is not used further in this chapter. In contrast, species assigned to the *Arthrobacter nicotianae* group form a distinct clade separate from other *Arthrobacter* species but without significant bootstrap support.

In the tree consisting of all *Arthrobacter* species and representatives of all genera assigned to the family *Micrococcaceae*, five subclades (which may be considered as genus-like clusters) can be identified. These subclades all have at least moderate bootstrap support. Subclade I is composed of *Arthrobacter antarcticus*, *Arthrobacter gangotriensis*, *Arthrobacter kerguelensis*, *Arthrobacter psychrophenolicus*, and *Arthrobacter sulfureus* with 84% bootstrap support. Since this subclade contains *Arthrobacter sulfureus*, the only representative of Komagata/Suzuki group VII, the other four species may also be assigned to this group. In fact, the peptidoglycan types of *Arthrobacter antarcticus*, *Arthrobacter gangotriensis*, *Arthrobacter kerguelensis*, and *Arthrobacter psychrophenolicus* support this assignment. Subclade II comprises six species, *Arthrobacter agilis*, *Arthrobacter flavus*, *Arthrobacter parietis*, *Arthrobacter subterraneus*, *Arthrobacter tecti*, and *Arthrobacter tumbae* with 89% bootstrap support. Subclade III is formed by *Arthrobacter citreus* (originally assigned to the *Arthrobacter globiformis*/*Arthrobacter citreus* group Keddie et al., 1986) or Komagata/Suzuki group V (Komagata and Suzuki, 1987), *Arthrobacter luteolus*, *Arthrobacter gandaviensis*, and *Arthrobacter koreensis* with 76% bootstrap support. A very stable subclade IV with 99% bootstrap support consists of *Arthrobacter alpinus*, *Arthrobacter psychrochitiniphilus*, *Arthrobacter psychrolactophilus*, and *Arthrobacter stackebrandtii*. Subclade V (100% bootstrap support) is composed of the two described *Sinomonas* species *Sinomonas flava* and *Sinomonas atrocyanea* (formerly named *Arthrobacter atrocyaneus* and assigned to *Arthrobacter globiformis*/*Arthrobacter citreus* group and Komagata/Suzuki group IV (Zhou et al., 2009), *Arthrobacter albidus*, and *Arthrobacter echigonensis*. The type species of the genus, *Arthrobacter globiformis*, is not assigned to any of these subclades or any other groups of species whose relatedness is supported by high bootstrap values (>75%), including *Arthrobacter humicola*/*Arthrobacter oryzae*, *Arthrobacter pigmenti*/*Arthrobacter castelli*, *Arthrobacter defluvii*/*Arthrobacter niigatensis*, *Arthrobacter bergerei*/*Arthrobacter ardleyensis*, and *Arthrobacter albus*/*Arthrobacter cumminsii*.

Several groups composed of species sharing high similarities (>97%) in their 16S rRNA gene sequences can also be identified. These rRNA similarity groups are not confirmed upon phylogenetic analyses and are here designated rRNA clusters, which distinguished them from the subclades. rRNA cluster 1 comprises *Arthrobacter globiformis*, *Arthrobacter pascens*, *Arthrobacter humicola*, and *Arthrobacter oryzae*, which share 98.4–99.5% sequence similarity. Two species of this cluster are also classified in the *Arthrobacter globiformis*/*Arthrobacter citreus* group and Komagata/Suzuki group III. Species assigned to rRNA cluster 2 are *Arthrobacter histidinolovorans*, *Arthrobacter nicotinovorans*, *Arthrobacter ureafaciens*, *Arthrobacter ilicis*, *Arthrobacter aurescens*, and *Arthrobacter nitroguajacolicus*; and sequence similarities are in the range 97.6–99.7%. This cluster contains species of the *Arthrobacter globiformis*/*Arthrobacter citreus* group and all species assigned to Komagata/Suzuki group II. rRNA cluster 3 comprises *Arthrobacter chlorophenolicus*, *Arthrobacter sulfonivorans*, *Arthrobacter oxydans*, *Arthrobacter defluvii*, *Arthrobacter polychromogenes*, *Arthrobacter scleromae*, *Arthrobacter niigatensis*, and *Arthrobacter phenanthrenivorans*, with sequence similarities in the range of 97.3–99.7%. The cluster contains one species assigned to the *Arthrobacter globiformis*/*Arthrobacter citreus* group and two species assigned to Komagata/Suzuki group I. rRNA cluster 4 species share 96.7–99.7% sequence similarity. This cluster contains the species *Arthrobacter arilaitensis*, *Arthrobacter ardleyensis*, *Arthrobacter bergerei*, *Arthrobacter creatinolyticus* *Arthrobacter mysorens*, *Arthrobacter nicotianeae*, *Arthrobacter protophormiae*, *Arthrobacter soli*, and *Arthrobacter uratoxydans*. Three of

these species were originally in the *Arthrobacter nicotianae* group and Komagata/Suzuki group VI. Notably, *Arthrobacter bergerei* shares high sequence similarity of 96.6–97.0% with some subclade I species, and subclade I species *Arthrobacter antarcticus*, *Arthrobacter psychrophenolicus*, and *Arthrobacter kerguelensis* also share sequence similarity values in the range 96.7–97.1% with some rRNA cluster 4 species.

In a study on genetic diversity among *Arthrobacter* species collected from terrestrial deep-subsurface sediments, partial *recA* gene sequences were obtained from strains of 14 *Arthrobacter* species (van Waasbergen et al., 2000). Unfortunately, in this study only 360 nucleotides of each strain were analyzed, and hence the deduced phylogeny is of limited statistical significance. However, these phylogenetic analyses demonstrated a close relationship between these groups of *Arthrobacter* species, *Arthrobacter sulfureus/Arthrobacter uratoxydans/Arthrobacter protophormiae/Arthrobacter nicotianae*, *Arthrobacter pascens/Arthrobacter globiformis*, *Arthrobacter aurescens/Arthrobacter nicotinovorans/Arthrobacter histidinolovorans/Arthrobacter ureafaciens*, and *Arthrobacter oxydans/Arthrobacter polychromogenes*, supporting the 16S rRNA based phylogeny. The low sequence similarity of the *Arthrobacter agilis* and *Arthrobacter citreus* genes to those from the other species also agrees with the findings of 16S rRNA studies. Interestingly, two species of *Micrococcus*, *Micrococcus luteus* and *Micrococcus lylae*, were clearly distinguished from all of the *Arthrobacter* species examined. In contrast, the 16S rRNA gene trees do not clearly distinguish these species from *Arthrobacter* (Figure 137). In other studies, the *recA* gene phylogeny also suggests a high degree of relatedness between *Arthrobacter phenanthrenivorans*, *Arthrobacter oxydans*, and *Arthrobacter polychromogenes*, which is similar to the 16S rRNA phylogeny (Kallimanis et al., 2009). Lastly, on the basis of its *recA* sequence, *Arthrobacter chlorophenolicus* does not appear to be closely related to other *Arthrobacter* species.

Chemotaxonomy. Fatty acid profiles of *Arthrobacter* species are composed predominantly of iso- and anteiso-branched fatty acids. The majority of species exhibit fatty acid profiles dominated by $C_{15:0}$ anteiso and possessing usually high amounts of $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Several species also possess significant amounts of $C_{16:0}$, including *Arthrobacter citreus*, *Arthrobacter nicotianae*, *Arthrobacter cumminsii*, *Arthrobacter niigatensis*, *Arthrobacter oxydans*, and *Arthrobacter polychromogenes*. However, the presence of this fatty acid is not correlated with genetic relatedness. Moreover, *Arthrobacter russicus* possesses an unusual fatty acid profile dominated by $C_{17:0}$ anteiso, but this trait has not been reported in its closest relative *Renibacterium salmonniarum*, which also possesses large amounts of $C_{15:0}$ anteiso (Embley et al., 1983). Therefore, while the fatty acid data may be useful for characterization and identification of *Arthrobacter* species, it does not correlate well with phylogenetic relationships between closely related species.

Arthrobacter species can be distinguished into two major groups based on the presence of monosaturated or completely unsaturated quinones. The first group includes the majority of *Arthrobacter* species, which possess monosaturated menaquinone with nine isoprenoic units in the side chain, MK-9(H_2). This group also includes a smaller number of species with predominantly MK-8(H_2) and corresponds to the polyphyletic *Arthrobacter globiformis/Arthrobacter citreus* group of Keddie et al. (1986). The second group includes several *Arthrobacter* species that exhibit menaquinones with eight, nine, and/or ten completely unsaturated isoprenoic units (MK-8, MK-9, and MK-10) and corresponds to the *Arthrobacter nicotianae* group (Keddie et al., 1986). Since the designation of these groups, all newly proposed *Arthrobacter* species with completely unsaturated menaquinones have proven to be phylogenetically related to the *Arthrobacter nicotianae* group. Species of the *Arthrobacter nicotianae* group (Keddie et al., 1986) whose menaquinone system have been analyzed include *Arthrobacter nicotianae*, *Arthrobacter creatinolyticus*, *Arthrobacter protophormiae*, *Arthrobacter sulfureus*, *Arthrobacter gangotriensis*, *Arthrobacter psychrophenolicus*, *Arthrobacter antarcticus*, and *Arthrobacter kerguelensis*. Unfortunately, the menaquinones of many related species of this group, such as *Arthrobacter arilaitensis*, *Arthrobacter bergerei*, *Arthrobacter mysorens*, *Arthrobacter rhombi*, and *Arthrobacter soli*, have not been examined. However, it would not be surprising if these latter species also possess completely unsaturated quinones.

Several *Arthrobacter* species exhibit quinone systems unusual for the genus. *Arthrobacter koreensis* (subclade III) was reported to have a quinone system with almost equal amounts (43:35) of MK-8(H_2) and MK-9(H_2). Other members of subclade III, *Arthrobacter luteolus* and *Arthrobacter citreus*, were reported to contain a different ratio of MK-8(H_2) and MK-9(H_2), 22:68 and 30:67, respectively (Collins and Kroppenstedt, 1983; Lee et al., 2003), which might reflect their close relatedness. Another quinone system with also almost equal amounts of MK-9(H_2) and MK-8(H_2), a ratio of 56:44, was reported for *Arthrobacter nasiphocae* (Collins et al., 2002a), which was not placed in any of the subclades above. *Arthrobacter albus* and *Arthrobacter cumminsii*, which are phylogenetically quite distant from the type species of the genus (Figure 137), exhibit the major menaquinone MK-8(H_2) (Busse, unpublished results). Species of subclade III, *Arthrobacter parietis*, *Arthrobacter subterraneus*, *Arthrobacter tecti*, and *Arthrobacter tumbae* share a quinone system with largely MK-9(H_2) and significant amounts (>20%) of MK-10(H_2), but this quinone system is also found in the distant relative *Arthrobacter stackebrandtii*. A quinone system most unusual among arthrobacters and many other bacteria was reported for *Arthrobacter scleromae*. It consists of unsaturated and saturated menaquinones of MK-8(H_2) and minor amounts of MK-10 (ratio of 88:12) (Huang et al., 2005b). Likewise, the quinone system of *Arthrobacter phenanthrenivorans* consists of MK-8 and MK-9(H_2) in a ratio 3.6:1 (Kallimanis et al., 2009). Because quinone systems composed of monosaturated and completely unsaturated menaquinones with isoprenoic side chains of different lengths are most unusual among bacteria, re-analyses would be desirable to confirm these two quinone systems.

The peptidoglycans of *Arthrobacter* species contain the diagnostic diamino acid lysine. Applying the scheme of Schleifer and Kandler (1972), differences in the amino acid composition of the interpeptide chains distinguish *Arthrobacter* species into two major groups. The majority of species exhibit peptidoglycan type A3α, which possess monocarboxylic L-amino acids or glycine or both in the interpeptide bridge. *Arthrobacter* species with type A3α peptidoglycan can be distinguished based on the amino acid composition in the interpeptide bridge. *Arthrobacter* species of subclade II and III are characterized by an interpeptide bridge consisting of Lys–Thr–$Ala_{2–3}$. Subclade II species *Arthrobacter agilis*, *Arthrobacter flavus*, *Arthrobacter subterraneus*, *Arthrobacter tecti*, and *Arthrobacter tumbae* possess Lys–Thr–Ala_3,

while *Arthrobacter parietis* possesses Lys–Thr–Ala_2. Subclade III species (*Arthrobacter citreus*, *Arthrobacter gandavensis*, *Arthrobacter koreensis*, and *Arthrobacter luteolus*) also possess Lys–Thr–Ala_2. Other species, *Arthrobacter psychrolactophilus* and *Arthrobacter alpinus* grouped in subclade IV, are also characterized by an interpeptide bridge of Lys–Thr–Ala_3. This interpeptide bridge may also be present in *Arthrobacter psychrochitiniphilus*, whose composition is known to be Lys, Thr, and Ala.

Species of *Arthrobacter* rRNA cluster 2 (*Arthrobacter aurescens*, *Arthrobacter histidinolovorans*, *Arthrobacter ilicis*, *Arthrobacter nicotinovorans*, *Arthrobacter nitroguajacolicus*, and *Arthrobacter ureafaciens*) exhibit an interpeptide bridge of Lys–Ala–Thr–Ala. Another similar interpeptide bridge (Lys–Ser–Thr–Ala) is found in *Arthrobacter chlorophenolicus*, *Arthrobacter sulfonivorans*, *Arthrobacter oxydans*, *Arthrobacter defluvii*, *Arthrobacter polychromogenes*, *Arthrobacter scleromae*, and probably also *Arthrobacter niigatensis* and *Arthrobacter alkaliphilus*. For the latter two species only the predominant amino acids of Lys, Ser, Thr, and Ala were reported (Ding et al., 2009). Except *Arthrobacter alkaliphilus*, which shares highest 16S rRNA gene similarity with *Arthrobacter methylotrophus* (97.4%), these species are grouped in rRNA cluster 3. The peptidoglycan of *Arthrobacter albidus* and *Arthrobacter echigonensis* is composed of the amino acids Lys, Ser, and Ala (Ding et al., 2009), which is consistent with a peptidoglycan interpeptide bridge of Lys–Ser–Ala_x and placement of these two species in subclade V together with the species of the genus *Sinomonas*.

Among arthrobacters, *Arthrobacter nasiphocae* and *Arthrobacter roseus* possess a unique interpeptide bridge composed of Lys–Ala_2–$Gly_{2–3}$–Ala (Gly) and Lys–Gly–Ala_3, respectively, which might reflect their distant phylogenetic relationship to other *Arthrobacter* species. The presence of serine in the interpeptide bridge of *Arthrobacter castelli* (Lys–Ala–Ser–Ala_3) distinguishes this species from its closest relative *Arthrobacter pigmenti*, which possesses Lys–Ala_4 in the interpeptide chain. Nevertheless, the presence of four alanine residues in the interpeptide bridges of both *Arthrobacter castelli* and *Arthrobacter pigmenti* may support the close relatedness of the two species. Other *Arthrobacter* species with interpeptide bridges composed of only alanine in addition to lysine are distributed throughout the genus. These species are *Arthrobacter crystallopoietes* (Lys–Ala), *Arthrobacter pascens* (Lys–Ala_2), *Arthrobacter stackebrandtii* (Lys–Ala_2), *Arthrobacter humicola* (Lys–$Ala_{>2}$), *Arthrobacter oryzae* (Lys–$Ala_{>2}$), *Arthrobacter globiformis* (Lys–Ala_3), *Arthrobacter russicus* (Lys–Ala_2), *Arthrobacter methylotrophus* (Lys–$Ala_{2–4}$), *Arthrobacter monumenti* (Lys–Ala_4), *Arthrobacter pigmenti* (Lys–Ala_4), and *Arthrobacter ramosus* (Lys–Ala_4). *Arthrobacter globiformis*, *Arthrobacter humicola*, *Arthrobacter oryzae*, and *Arthrobacter pascens* are grouped in rRNA cluster 1, and this grouping is supported by the intepeptide composition. In contrast, 16S rRNA analyses do not suggest assignment of the remaining species to rRNA cluster 1. Instead, relatedness to species with different interpeptide bridge compositions is indicated. Hence, this type of interpeptide bridge appears to be less significant for grouping of *Arthrobacter* than other interpeptide bridge structures.

The other major peptidoglycan type found in *Arthrobacter* species is A4α, which contains glutamic acid or glutamic acid and alanine in the interpeptide bridge. It is found in all species in the *Arthrobacter nicotianae* group (species of subclade I and rRNA cluster 4) and in *Arthrobacter rhombi*. Many phylogenetic trees place *Arthrobacter rhombi* at the root of the *Arthrobacter nicotianae* group, but bootstrap support is lacking for assignment to this group (Figure 137). Nevertheless, the type of interpeptide bridge Lys–Ala–Glu supports its affiliation with rRNA cluster 4. Species of subclade I, *Arthrobacter sulfureus*, *Arthrobacter antarcticus*, *Arthrobacter gangotriensis*, *Arthrobacter psychrophenolicus*, and *Arthrobacter kerguelensis*, possess an interpeptide bridge of Lys–Glu. Peptidoglycan type A4α with L-glutamic acid in the interpeptide bridge is also present in *Arthrobacter cumminsii* and *Arthrobacter albus*, which together occupy a phylogenetically distinct branch within the radiation of *Arthrobacter* species (Figure 137). Another species with peptidoglycan type A4α is *Arthrobacter woluwensis*. In this case, the dicarboxylic acid in the interpeptide bridge is D-aspartic acid, which (so far) is a unique trait within the genus *Arthrobacter* but this trait was already reported in *Micrococcus flavus* and a strain of *Micrococcus luteus* (Liu et al., 2007; Wieser et al., 2002).

Cell-wall sugars have been analyzed for approximately half of *Arthrobacter* species, and so far 14 different sugar compositions have been reported. The majority of species possess galactose (Gal) solely or in combination with other sugars, such as glucose (Glc), rhamnose (Rha), mannose (Man), ribose (Rib), and xylose (Xyl). Gal alone is present in the cell walls of *Arthrobacter tumbae*, *Arthrobacter parietis*, and *Arthrobacter citreus*. The cell walls of the type species of the genus, *Arthrobacter globiformis*, and its close relative *Arthrobacter pascens* contain Gal and Glc, and these sugars are also found in *Arthrobacter oryzae*, *Arthrobacter crystallopoietes*, *Arthrobacter histidinolovorans*, *Arthrobacter oxydans*, *Arthrobacter scleromae*, *Arthrobacter nicotianae*, and *Arthrobacter sulfureus*. *Acaricomes phytoseiuli*, which is phylogenetically placed within the radiation of the genus *Arthrobacter*, also possesses these sugars. *Arthrobacter tecti*, *Arthrobacter aurescens*, *Arthrobacter alpinus*, and *Arthrobacter ureafaciens* possess Gal and minor amounts of Man. *Arthrobacter humicola* and *Arthrobacter pigmenti* possess Gal and Rha in their cell walls. The cell wall of *Arthrobacter defluvi* contains Gal, Glc, and Rha. The cell walls of *Arthrobacter subterraneus* and *Arthrobacter flavus* contain Gal, Glc, and Rib. The cell walls of *Arthrobacter ramosus* and *Arthrobacter ilicis* possess Gal, Man, and Rha.The cell walls of *Arthrobacter monumenti* and *Arthrobacter castelli* possess minor amounts of Xyl and Rha in addition to Gal. Four cell-wall sugars, Gal, Glc, Rib, and Rha were detected in *Arthrobacter roseus*, and Gal, Glc, Man, and Rib were found in *Arthrobacter arilaitensis*. Several species lack Gal in the cell wall. Only one cell-wall sugar was detected in *Arthrobacter psychrophenolicus* (Glc) and *Arthrobacter koreensis* and *Arthrobacter luteolus* (Rha). *Arthrobacter agilis* is the sole *Arthrobacter* species which contains glucosamine (GlcN). Three cell-wall sugars, Glc, Man, and Rib, are present in *Arthrobacter bergerei*. Since the cell-wall sugar composition varies among closely related *Arthrobacter* species or certain sugar compositions are found in different subclades/rRNA clusters, apparently this feature is more suitable for characterization of species rather than for identification of closely related groups.

In a study of distribution and composition of teichoic acids, Fiedler and Schäfler (1987) showed that these components are found in the cell walls of A4α peptidoglycan type arthrobacters (*Arthrobacter nicotianae* group *sensu* Keddie et al., 1986), but

not in other representatives of the genus. The teichoic acids of *Arthrobacter nicotianae* are composed of glycerol, glucose, and glucosamine. A qualitatively similar teichoic acid composition is also present in a strain of *Arthrobacter mysorens*, whereas *Arthrobacter protophormiae* and *Arthrobacter sulfureus* also possess galactosamine. It might be assumed that the teichoic acids contribute to the cell-wall sugars, but surprisingly the glucosamine of the teichoic acids of *Arthrobacter nicotianae* and *Arthrobacter sulfureus* was not reported among the cell-wall sugars (Stackebrandt et al., 1983b). Unfortunately, the teichoic acids of only a very limited number of species have been analyzed. Hence, the importance of this tool for classification is unclear.

Information regarding polar lipid composition of arthrobacters is also rather limited. All *Arthrobacter* species which have been examined possess phosphatidylglycerol and diphosphatidylglycerol. In addition, phosphatidylinositol and several glycolipids may be present. In an early study, Walker and Bastl (1967) identified the glycolipids of *Arthrobacter globiformis* strain 616 as dimannosyl-diglyceride, monogalactosyl-diglyceride, and digalactosyl-diglyceride. They also found some evidence for the presence of small amounts of a trimannosyl diglyceride and an even smaller quantity of a tetramannosyl-diglyceride. In a following study, Shaw and Stead (1971) analyzed the lipid composition of the type strains of *Arthrobacter crystallopoietes* and *Arthrobacter pascens* as well as *Arthrobacter globiformis* strain 616. The polar lipid profile of *Arthrobacter crystallopoietes* was composed of phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, dimannosyl-diglyceride, monogalactosyl-diglyceride, digalactosyl-diglyceride, and a fourth glycolipid supposed to be tetramannosyl-diglyceride. No significant differences were reported for *Arthrobacter pascens* and *Arthrobacter globiformis*. These data confirm the close phylogenetic relatedness of *Arthrobacter globiformis* and *Arthrobacter pascens* and may imply relatedness to *Arthrobacter crystallopoietes*, which does not occupy a stable position in phylogenetic trees. The polar lipid profile of *Arthrobacter ilicis* consists of phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and two unidentified glycolipids G_A and G_B (Collins et al., 1981). The polar lipids of the type strains of *Arthrobacter aurescens*, *Arthrobacter citreus*, *Arthrobacter crystallopoietes*, *Arthrobacter globiformis*, and *Arthrobacter polychromogenes* also comprise phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and varying numbers of unidentified glycolipids (Collins et al., 1982a). The number of *Arthrobacter globiformis* glycolipids (although not analyzed for chemical structure) was in agreement with the number in previous reports. Collins et al. (1982a) detected only three glycolipids in *Arthrobacter cyrstallopoietes*, but already Shaw and Stead (1971) mentioned the low amounts of a fourth glycolipid in this species. *Arthrobacter aurescens* and *Arthrobacter polychromogenes* showed three unidentified glycolipids, whereas in *Arthrobacter citreus* only two glycolipids were detected.

Collins and Kroppenstedt (1983) investigated the polar lipid profiles of the type strains of *Arthrobacter citreus*, *Arthrobacter nicotianae*, *Arthrobacter protophormiae*, *Arthrobacter sulfureus* (formerly *Brevibacterium sulfureus*) and found polar lipid profiles consisting of phosphatidylglycerol, diphosphatidylglycerol, and unidentified glycolipids, either G_a or G_b. These two glycolipids showed chromatographic behaviors of diglycosyldiacylglycerol, and their staining behavior indicated the presence of galactose and/or mannose residues. Unidentified glycolipid G_a was detected in *Arthrobacter nicotianae*, *Arthrobacter protophormiae*, and *Arthrobacter citreus*, whereas G_b was found in *Arthrobacter sulfureus*. *Arthrobacter citreus* was the only species of this group which possessed phosphatidylinositol. The distribution of G_a and G_b among species of the *Arthrobacter nicotianae* group, here represented by *Arthrobacter nicotianae*, *Arthrobacter protophormiae* and *Arthrobacter sulfureus*, is in accordance with the subdivision of this group based on phylogeny and peptidoglycan type (Lys–Ala–Glu or Lys–Glu). The lipids of *Arthrobacter psychrophenolicus*, placed with *Arthrobacter sulfureus* in subclade I (Figure 137), are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and an unidentified glycolipid (Margesin et al., 2004). Unfortunately, no information is provided concerning the chromatographic behavior of this unidentified glycolipid which would allow a comparison to G_b. However, the presence of phosphatidylinositol distinguishes *Arthrobacter psychrophenolicus* from its close relative *Arthrobacter sulfureus*. The unidentified glycolipid G_A of *Arthrobacter ilicis* shows a chromatographic behavior similar to G_a mentioned above, whereas the chromatographic behavior of G_B of *Arthrobacter ilicis* suggests that it is different from G_b. *Arthrobacter russicus* is characterized by the predominant lipids diphosphatidylglycerol and phosphatidylinositol and lesser amounts of phosphatidylglycerol (Li et al., 2004c). In addition to possessing phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol, *Arthrobacter castelli*, *Arthrobacter monumenti* and *Arthrobacter pigmenti* possess one unidentified phospholipid, and one unidentified glycolipid; *Arthrobacter parietis* possesses one unidentified phospholipid and two unidentified glycolipids; and *Arthrobacter tecti* and *Arthrobacter tumbae* possess one unidentified phospholipid (Heyrman et al., 2005). *Arthrobacter flavus*, *Arthrobacter roseus*, and *Arthrobacter phenanthrenivoras* were reported to possess phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylethanolamine (Kallimanis et al., 2009; Reddy et al., 2000; Reddy et al., 2002). Phosphatidylethanolamine is rare among species of *Arthrobacter* and related genera as is the absence of phosphatidylinositol. Re-analysis of the polar lipid profile did not provide any indication of the presence of phosphatidylethanolamine in the type strain of *Arthrobacter roseus*. Like other arthrobacters, the type strain of *Arthrobacter roseus* had a polar lipid profile containing predominantly diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and an unidentified glycolipid (Busse, unpublished results). Nevertheless, the variability in polar lipid composition suggest that, while this trait is useful for classification of arthrobacters, current data are not complete enough to demonstrate that the distribution of polar lipids is dependent on phylogenetic relatedness.

Information concerning polyamine patterns, which are often useful for classification of bacteria, is limited. Altenburger et al. (2002) analyzed polyamines of 13 *Arthrobacter* species, but the results were not very useful for classification. Spermidine was the most abundant polyamine in most species. While significant differences in the overall polyamine content were detected, the polyamine content was not in accordance with relationships deduced from phylogeny or other chemotaxonomic markers.

Pathogenicity. Although soil is considered the major habitat of arthrobacters, strains have been also isolated from clinical specimens and may have been previously identified as CDC coryneform group B-1 and B-3 (Funke et al., 1997b). Thus, several *Arthrobacter* strains now have been reported to be associated with human diseases.

Arthrobacter cumminsii strains were isolated from urine, a skin infection (Funke et al., 1996), a urinary tract infection, chronic otorrhea, infected amniotic fluid, a vaginal swab, calcaneus osteomyelitis, external otitidis, a deep tissue infection of the upper leg, chronic cervicitis, a blood culture, and a leg wound (Funke et al., 1998). A strain of *Arthrobacter woluwensis* was isolated from blood of an HIV-infected patient hospitalized with fever and chills (Funke et al., 1996) and found to cause a subacute infective endocarditis with involvement of the native mitral valve of an HIV-seronegative injection drug user (Bernasconi et al., 2004) and a catheter-related bacteremia (Shin et al., 2006). Wauters et al. (2000a) reported isolation and characterization of the newly described species *Arthrobacter luteolus* (one strain) and *Arthrobacter albus* (two strains) from an infected surgical wound, and urine and blood from a patient with severe phlebitis, respectively, and detected *Arthrobacter oxydans* (two strains) in blood specimens. The species *Arthrobacter creatinolyticus* was identified in a screening for creatinine-hydrolyzing bacteria from patients with unusually low levels of creatinine in urine samples (Hou et al., 1998), and *Arthrobacter scleromae* was isolated from bloody effusion of a swollen scleroma (Huang et al., 2005b). A bacterial strain associated with a case of Whipple's syndrome in a patient with severe chronic uveitis and systemic inflammatory manifestations was classified within the genus *Arthrobacter* based on partial 16S rRNA gene sequence comparison (Bodaghi et al., 1998). Unnamed *Arthrobacter* strains were recovered from blood cultures or reported to be associated with vaginitis and endophthalmitis (Esteban et al., 1996; Funke et al., 1996). Another unnamed *Arthrobacter* strain was isolated from the blood of a neutropenic patient with acute lymphoblastic leukemia (Hsu et al., 1998).

Among 50 strains of large-colony-forming, whitish-grayish, non-cheese-like-smelling, nonfermentative Gram-stain-positive rods encountered from human clinical specimens, Mages et al. (2008) identified 38 strains of the genus *Arthrobacter*. Fourteen strains isolated from blood, urine, otitis externa, cervix, wound swab, and a tracheal secretion were close relatives of *Arthrobacter cumminsii*. Eleven strains isolated from a blood culture, lung swab after autopsy, eye, vaginal swab, wound swab, or unknown source were closely related to *Arthrobacter oxydans*.

Close relatives of *Arthrobacter aurescens* were recovered from urine and an unknown clinical source. One strain isolated from neck abscess was affiliated with *Arthrobacter oryzae*, two strains related to *Arthrobacter albus* were isolated from blood culture and urine, one strain related to *Arthrobacter protophormiae* was isolated from urine, and some strains with unclear species affiliations were present in specimens from various blood cultures and a hand wound. The novel species *Arthrobacter sanguinis* was also isolated from blood (Mages et al., 2008).

These studies demonstrate that arthrobacters may cause disease in humans and that at least the species *Arthrobacter cumminsii* and *Arthrobacter oxydans* are opportunistic pathogens. Moreover, the pathogenic potential of *Arthrobacter albus*, *Arthrobacter woluwensis*, *Arthrobacter arborescens*, *Arthrobacter oryzae*, *Arthrobacter protophormiae*, and *Arthrobacter sanguinis* should be studied in more detail.

Arthrobacters are generally sensitive to antibiotics. However, only few reports exist on the susceptibility of arthrobacters to antibiotics. Among 24 *Arthrobacter* strains (including the type strains of *Arthrobacter globiformis*, *Sinomonas atrocyanea* [formerly *Arthrobacter atrocyaneus*], *Arthrobacter aurescens*, *Arthrobacter crystallopoietes*, *Arthrobacter cumminsii*, *Arthrobacter histidinolovorans*, *Arthrobacter nicotinovorans*, *Arthrobacter oxydans*, *Arthrobacter pascens*, *Arthrobacter ureafaciens*, *Arthrobacter nicotianeae*, *Arthrobacter protophormiae*, *Arthrobacter uratoxydans*, and *Arthrobacter woluwensis*) tested for susceptibility to 16 antimicrobials (amoxicillin-clavulanic acid, ampicillin, ceftriaxone, cefuroxime, cefalothin, chloramphenicol, ciprofloxacin, clindamycin, erythromycin, gentamicin, imipenem, penicillin G, rifampin, teichoplanin, tetracycline, and vancomycin), only the strain of *Arthrobacter woluwensis* was multidrug resistant. It was only susceptible to teichoplanin, tetracycline, and vancomycin (Funke et al., 1996). The susceptibility patterns of 38 *Arthrobacter* strains was also studied by Mages et al. (2008). Nearly all strains were susceptible to β-lactams, doxycycline, gentamicin, linezolid, rifampin, and vancomycin. Additional strains of *Arthrobacter woluwensis* examined in the latter study were not multidrug resistant, indicating that this trait was not characteristic of the species.

Differentiation of the genus *Arthrobacter* from other genera

Differentiation of the genus *Arthrobacter* from distantly related genera which share phenotypic properties that could lead to misidentifications (e.g. genera of the family *Microbacteriaceae*, *Brevibacterium*, or *Corynebacterium*) can be unambiguously achieved by 16S rRNA gene sequence analyses. Support for phylogenetic relationshhips based on 16S rRNA analyses may be obtained from analyses of the peptidoglycan type, quinone system, and polyamines. Members of the family *Microbacteriaceae* possess exclusively B type peptidoglycan, usually containing ornithine, diaminobutyric acid, or lysine as the diagnostic diamino acid. Completely unsaturated menaquinones with 9–14 isoprenoic units are also useful for differentiation from the majority of *Arthrobacter* species. The polyamine pattern of *Arthrobacter* differentiates it from certain genera, such as *Agrococcus*, *Brevibacterium*, and *Pseudoclavibacter helvolus*, whose polyamine patterns are predominated by spermine, putrescine, or cadaverine (Altenburger et al., 1997; Manaia et al., 2004; Wieser et al., 1999; Zlamala et al., 2002). Differentiation of *Arthrobacter* from other genera of the *Micrococcaceae* is hampered because *Arthrobacter* is not monophyletic and possesses significant phenotypic heterogeneity, especially for chemotaxonomic markers such as the interpeptide chains in the peptidoglycan and quinone systems. Hence, 16S rRNA based phylogeny and sequence similarities do not unambiguously allow identification at the genus level.

The majority of *Arthrobacter* species, except *Arthrobacter cumminsii*, *Arthrobacter albus*, and *Arthrobacter scleromae*, can be distinguished from members of the genus *Micrococcus* by the predominance of MK-7(H_2), MK-8, and/or MK-8(H_2) in the latter genus. Except for *Arthrobacter woluwensis*, which contains L-Lys–D-Asp, no *Arthrobacter* species has a peptidoglycan interpeptide bridge similar to that of *Micrococcus* species, which consists of L-Lys–D-Asp or L-Lys–polymerized peptide subunit (subgroup A2; Schleifer and Kandler, 1972). The only representative of the genus *Acaricomes* contains a MK-10(H_2) quinone system, which has been reported in moderate or low amounts in only a few *Arthrobacter* species.

The MK-9(H_2) quinone system of *Citricoccus* is common in the majority of *Arthrobacter* species, but it distinguishes *Citricoccus* from *Arthrobacter* species with completely unsaturated menaquinones. The peptidoglycan of *Citrobacter* species contains an interpeptide chain composed of Lys–Gly–Glu, which is

not known for *Arthrobacter*, and allows a reliable differentiation between the two genera. *Kocuria* species form a rather stable rRNA gene clade within the *Micrococcaceae*, and phylogenetic analyses can differentiate this genus. The majority of *Arthrobacter* species are also distinguished from *Kocuria* based on the amino acid composition of the interpeptide bridge, which consists of Lys–$Ala_{3–4}$ in *Kocuria*. The same or similar interpeptide bridges are present within *Arthrobacter globiformis* and its close relatives *Arthrobacter pascens*, *Arthrobacter humi*, and *Arthrobacter oryzae* as well as *Arthrobacter crystallopoietes*, *Arthrobacter stackebrandtii*, *Arthrobacter methylotrophicus*, *Arthrobacter russicus*, *Arthrobacter ramosus*, *Arthrobacter monumenti*, and *Arthrobacter pigmenti*. Because of the variability of quinone systems among *Kocuria* species, which includes MK-7(H_2), MK-8(H_2), MK-9(H_2), or combinations of two of these components, this characteristic only distinguishes it from *Arthrobacter* species that possess completely unsaturated menaquinones.

Arthrobacter species with mono-saturated menaquinones can be unambiguously distinguished from *Nesterenkonia* because this genus contains only unsaturated menaquinones (MK-7, MK-8, or a combination of MK-7, MK-8, and MK-9). Differentiation of *Arthrobacter* species with completely unsaturated menaquinones from the majority of *Nesterenkonia* species can be achieved based on the length of the isoprenoic chain. While MK-8 and MK-9 are major components in certain *Arthrobacter* species, they are only reported for *Nesterenkonia flava* and *Nesterenkonia alba* (Luo et al., 2008; Luo et al., 2009). However, these two species have a peptidoglycan containing the interpeptide bridge Lys–Gly–Asp, which is not found in any *Arthrobacter* species. All *Nesteronkonia* species except *Nesteronkonia lacusekhoensis*, which contains a peptidoglycan with Lys–Glu in the interpeptide bridge, can be distinguished from *Arthrobacter* species because the former have an interpeptide bridge of Lys–Gly–Asp or Lys–Gly–Glu.

The peptidoglycan interpeptide bridge consisting of Lys–Gly–Ala (Kusser and Fiedler, 1983) and menaquinone MK-9 of *Renibacterium* distinguishes it from *Arthrobacter*. Also *Rothia* species can be reliably differentiated from *Arthrobacter* because MK-7 is the predominant menaquinone and Lys–Ala is the peptidoglycan interpeptide bridge, the latter only being found in *Arthrobacter crystallopoietes*.

It is harder to differentiate *Arthrobacter* from *Zhihengliuella*. Similar to several *Arthrobacter* species, *Zhihengliuella* possesses a peptidoglycan interpeptide bridge with Lys–Ala–Glu and a quinone system dominated by MK-10 and MK- 9. The presence of the cell-wall sugar tyvelose in *Zhihengliuella* (Tang et al., 2009; Zhang et al., 2007) might be useful for differentiation, but cell-wall sugars have been analyzed only for a limited number of *Arthrobacter* species and the importance of this trait for differentiation has not been substantiated. The problem in differentiation might be related to the proposal of the genus *Zhihengliuella*. This genus was described based on phylogeny of the rRNA gene, but the branching from other taxa had only low bootstrap support (51%), and phenotypic traits distinguishing it from the *Arthrobacter nicotianae* group, which possesses similar or identical quinones and peptidoglycan structure, were provided without considering all the species of the group. For instance, the major fatty acids of *Zhihengliuella* are $C_{15:0}$ anteiso and $C_{15:0}$ iso. For the *Arthrobacter nicotianae* group, only $C_{15:0}$ anteiso was reported as a trait in the latter study. In fact, a number of *Arthrobacter nicotianae* group species contain both $C_{15:0}$ anteiso and $C_{15:0}$ iso as abundant fatty acids, such as *Arthrobacter uratoxydans*, *Arthrobacter protophormiae*, and *Arthrobacter sulfureus* (Funke et al., 1996). Moreover, *Zhihengliuella* species possess high 16S rRNA gene sequence similarities with *Arthrobacter* species from different groups. For instance, the similarities with species of the rRNA cluster 4 are in the range 96.0–97.0%, which is indicative of an affiliation with this rRNA cluster. Hence, the re-evaluation of the taxonomic status of the genus *Zhihengliuella* is desirable. Perhaps, analysis of *recA* or some other housekeeping genes will resolve its taxonomic status more clearly. A possible outcome of these studies may be the transfer of *Arthrobacter* with Lys–Ala–Glu in the interpeptide bridge to the genus *Zhihengliuella*.

Taxonomic comments

As presently defined, the genus *Arthrobacter* comprises species with significant phenotypic variability in their composition of quinones, peptidoglycan, cell-wall sugars and, to a lesser degree, polar lipids. In many cases, groupings based on shared certain chemotaxonomic traits are well supported by comparative 16S rRNA gene sequence analyses, and most intra-group 16S rRNA gene sequence similarities are above 96.0%. These results suggest the genus *Arthrobacter* should be dissected into a number of genera.

Based on phylogeny, 16S rRNA gene sequence similarities, peptidoglycan compositions and/or quinone systems, the following genus-like groups can be defined: "*Arthrobacter globiformis* group" (*Arthrobacter sensu stricto*; corresponding to rRNA cluster 1), "*Arthrobacter aurescens* group" (corresponding to rRNA cluster 2), "*Arthrobacter oxydans* group" (corresponding to rRNA cluster 3), "*Arthrobacter protophormiae* group" (corresponding to rRNA cluster 4), "*Arthrobacter sulfureus* group" (corresponding to subclade I), "*Arthrobacter agilis* group" (corresponding to subclade II), "*Arthrobacter citreus* group" (corresponding to subclade III), "*Arthrobacter psychrolactophilus* group" (corresponding to subclade IV), "*Arthrobacter pigmenti* group", "*Arthrobacter albus/ cumminsii* group", and "*Sinomonas* group" (corresponding to subclade V). Species assigned to the different groups and their major characteristics are listed in Tables 74–84, and their differential characteristics are given in Tables 85–95.

New groups proposed for the genus *Arthrobacter*

"*Arthrobacter globiformis* group" (*Arthrobacter sensu stricto*; rRNA cluster 1). Members of the *Arthrobacter* "*globiformis* group" (Table 74) exhibit 98.4–99.5% 16S rRNA gene similarity, a peptidoglycan type A3α (Lys–Ala_2 or Lys–Ala_3) and menaquinone MK-9(H_2). *Arthrobacter crystallopoietes* is preliminarily assigned to this group because it shares highest 16S rRNA gene sequence similarity (97.6%) with *Arthrobacter globiformis* and possesses a peptidoglycan composed of Lys–Ala. Table 85 lists differential characteristics for this group.

"*Arthrobacter aurescens* group" (rRNA cluster 2). Species of this group (Table 75) share high 16S rRNA similarities (>97.5%), peptidoglycan type A3α (Lys–Ala–Thr–Ala) and the menaquinone MK-9(H_2). Table 86 lists differential characteristics for this group.

"*Arthrobacter oxydans* group" (rRNA cluster 3). Close relatedness of the species of this group is indicated by high 16S rRNA gene similarities (>97%). The peptidoglycan type is A3α

TABLE 74. The "*Arthrobacter globiformis* group" (*Arthrobacter sensu stricto*; rRNA cluster 1) including tentatively assigned species *Arthrobacter crystallopoietes*, *Arthrobacter ramosus*, and *Arthrobacter methylotrophus*)[a,b,c]

	A. globiformis[d]	*A. pascens*[d]	*A. humicola*	*A. oryzae*	*A. crystallopoietes*[d]	*A. ramosus*	*A. methylotrophus*
Peptidoglycan type and interpeptide bridge	A3α, Lys–Ala_3	A3α, Lys–Ala_2	A3α, Lys–$Ala_{>2}$[e]	A3α, Lys–$Ala_{>2}$[e]	A3α, Lys–Ala	A3α, Lys–Ala_4	A3α, Lys–$Ala_{2–4}$
Quinone system	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2), [MK-10(H_2)][f]
Cell-wall sugars	Gal, Glc	Gal, Glc	Gal, Rha	Gal, Glc	Gal, Glc	Gal, Man, Rha	

[a]Abbreviations: Ala, alanine; Asp, aspartic acid; Glu, glutamic acid; Gly, glycine; Lys, lysine; Ser, serine; Thr, threonine; Gal, galactose; Glc, glucose; GlcN, glucosamine; Man, mannose; Rha, rhamnose; Rib, ribose; Xyl, xylose; MK-9(H_2) designates a menaquinone with nine isoprenoic units in the side chain, of which one unit is saturated.

[b]If not indicated otherwise data are taken from the original species description.

[c]98.4–99.5% 16S rRNA gene sequence similarities.

[d]Data from Schleifer and Kandler (1972), Keddie and Cure (1978), Collins and Jones (1981).

[e]Only quantitative amino acid composition of the peptidoglycan was reported (Kageyama et al., 2008). Peptidoglycan type is concluded from the amino acid composition.

[f]Compounds shown in brackets were detected in the range 5–19%.

TABLE 75. The "*Arthrobacter aurescens* group" (rRNA cluster 2)[a,b,c]

	A. aurescens	*A. histidinolovorans*	*A. ilicis*	*A. nicotinovorans*	*A. nitroguajacolicus*	*A. ureafaciens*
Peptidoglycan type and interpeptide bridge[d]	A3α, Lys–Ala–Thr–Ala	A3α, Lys–Ala–Thr–Ala	A3α, Lys–Ala–Thr–Ala	A3α, Lys–Ala–Thr–Ala	A3α, Lys–Ala–Thr–Ala	A3α, Lys–Ala–Thr–Ala
Quinone system[e]	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2)	MK-9(H_2), [MK-8(H_2), MK-10(H_2)][f]	MK-9(H_2)
Cell-wall sugars[g]	Gal, (Man)	Gal, Glc	Gal, Man, Rha		Gal, (Man)	Gal, (Man)

[a]For abbreviations, see footnote to Table 74.

[b]If not indicated otherwise, data are taken from the original species description.

[c]97.6–99.7% 16S rRNA gene sequence similarities.

[d]Data are from Schleifer and Kandler (1972) except *Arthrobacter nicotinovorans* and *Arthrobacter nitroguajaolicus*.

[e]Data are from Collins and Jones (1981) except *Arthrobacter nicotinovorans* and *Arthrobacter nitroguajaolicus*.

[f]Reported to be present in minor amounts.

[g]Sugars listed in parentheses are present only in minor amounts. Data are from Keddie and Cure (1978) except *Arthrobacter nicotinovorans* and *Arthrobacter nitroguajaolicus*.

(Lys–Ser–Thr–Ala). For most species, MK-9(H_2) is the major menaquinone, but MK-8(H_2) predominates in *Arthrobacter scleromae*. In *Arthrobacter phenanthrenivorans* both MK-8 and MK-9(H_2) are abundant (Table 76). Table 87 lists differential characteristics for this group.

"*Arthrobacter protophormiae* group" (rRNA cluster 4). The species of this group (Table 77) possess 16S rRNA gene similarities of 95.5–99.7%. Each species shares at least 96.7% similarity with another species within this group, but most values are higher than 97.5%. Members of this group share the peptidoglycan type A4α (Lys–Ala–Glu) and a quinone system composed of completely unsaturated menaquinones with eight and/or nine isoprenoic units and with MK-8 always predominant. *Arthrobacter rhombi* is assigned to this group based on peptidoglycan type. Table 88 lists differential characteristics for this group.

"*Arthrobacter sulfureus* group" (subclade I). The species in this group (Table 78) share at least 97.2% 16S rRNA gene similarity and form a robust clade supported by high bootstrap values in phylogenetic trees. Members of this group share the peptidoglycan type A4α (Lys–Glu) and a quinone system composed of completely unsaturated menaquinones, with MK-9 predominating but also usually significant amounts of MK-10. Table 89 lists differential characteristics for this group.

"*Arthrobacter agilis* group" (subclade II). Species comprising this group (Table 79) share 97.3–99.6% similarity in the 16S rRNA gene and form a subclade supported by high bootstrap values. The peptidoglycan type is A3α with Lys–Thr–$Ala_{2–3}$. MK-9(H_2) is the predominant menaquinone, but significant amounts of MK-10(H_2) are present in four species of the subclade. Table 90 lists differential characteristics for this group.

"*Arthrobacter citreus* group" (subclade III). Species comprising this group (Table 80) share 16S rRNA gene similarities of 97.6–98.9% and form a subclade supported by moderate bootstrap values. The peptidoglycan type is A3α with Lys–Thr–Ala_2. The quinone system comprises menaquinone MK-9(H_2) or almost equal amounts of MK-8(H_2) and MK-9(H_2). Table 91 lists differential characteristics for this group.

"*Arthrobacter psychrolactophilus* group" (subclade IV). Species comprising this group (Table 81) share >97.0% similarity in the 16S rRNA gene and form a robust clade supported by 99% bootstrap values. The interpeptide bridge of the peptidoglycan is either Lys–Thr–$Ala_{1–3}$ or Lys–Ala_2, and MK-9(H_2) is the predominant menaquinone. Moderate proportions of MK-10(H_2) may be present as well. Species of this group are psychrophilic or psychrotolerant and grow at 0–4°C. It is interesting that in a FASTA sequence comparisons among 28 database entries showing 97.8% or higher similarity with *Arthrobacter psychrochitiniphilus*, 26 sequences were from Antarctica, Spitzbergen, glaciers, or other sources likely to permit low temperature growth (Bai et al., 2006; Cheng and Foght, 2007; Hansen et al., 2007; Reddy et al., 2009; Srinivas et al., 2009). Hence, growth at low temperatures may be another trait of the members of this group. Table 92 lists differential characteristics for this group.

"*Arthrobacter pigmenti* group". The core of this group (Table 82) is represented by *Arthrobacter pigmenti* and *Arthrobacter castelli*, which share 97.9% 16S rRNA gene similarity. *Arthrobacter monumenti* is assigned to this group (96.2% similarity) although it shares higher 16S rRNA gene similarities (but still less than 97.0%) with some other *Arthrobacter* species. However, chemotaxonomic traits of *Arthrobacter monumenti* are in better agreement with those of *Arthrobacter pigmenti* and *Arthrobacter castelli*. *Arthrobacter monumenti* shares with *Arthrobacter pigmenti* and *Arthrobacter castelli* a peptidoglycan with four alanines in the interpeptide chain (Lys–Ala_4 or Lys–Ala–Ser–Ala_3) and the cell-wall sugars Gal and Rha. Notably, the same interpeptide bridge is found in some species of the "*Arthrobacter globiformis* group", including *Arthrobacter ramosus* and *Arthrobacter methylotrophus*. Thus, future studies might combine the "*Arthrobacter globiformis* group" and "*Arthrobacter pigmenti* group" or transfer species between the groups. Table 93 lists differential characteristics for this group.

"*Arthrobacter albus/cumminsii* group". So far, only two species (Table 83) are assigned to this group. They share 99.1% similarity in the 16S rRNA gene and higher sequence similarities with representatives of other genera, such as *Kocuria*, *Citricoccus*, and *Micrococcus*, than with other *Arthrobacter* species. The peptidoglycan type is A4α with Lys–Ala–Glu or Lys–Ser–(Gly)–Glu. The quinone system is MK-8(H_2). Table 94 lists differential characteristics for this group.

"*Sinomonas* group" (subclade V). The two species *Arthrobacter echinogenes* and *Arthrobacter albidus* (Table 84) form a clade with the two species of the genus *Sinomonas* (Zhou et al., 2009). The type strains of the two species share more than 97.0% 16S rRNA gene similarity with at least one of the two species of the genus *Sinomonas* and less than 94.5% similarity with other recognized *Arthrobacter* species. *Arthrobacter albidus* and *Arthrobacter echigonensis* possess Lys, Ser, and Ala in their peptidoglycan, which is consistent with the peptidoglycan type A3α (Lys–Ser–$Ala_{2–3}$) reported for *Sinomonas atrocyanea*. The menaquinone is MK-9(H_2). For these reasons, *Arthrobacter echinogenes* and *Arthrobacter albidus* should be transferred to the genus *Sinomonas*. Table 95 lists differential characteristics for this group.

Species not assigned to the above groups. Due to discrepancies between the 16S rRNA gene sequence and phenotypic data, several species remain ungrouped in this scheme, including *Arthrobacter alkaliphilus*, *Arthrobacter crystallopoietes*, *Arthrobacter methylotrophus*, *Arthrobacter nasiphocae*, *Arthrobacter ramosus*, *Arthrobacter roseus*, *Arthrobacter russicus*, *Arthrobacter sanguinis*, and *Arthrobacter woluwensis*. However, if priority is given to the chemotaxonomic characteristics, several species can be tentatively assigned to certain of the above-mentioned "*Arthrobacter* groups".

Arthrobacter alkaliphilus and *Arthrobacter methylotrophicus* form a separate line of descent within the radiation of the genus *Arthrobacter*. While the high 16S rRNA gene similarity of 97.4% suggest a close relationship, similarities with other species are not much lower, 97.1% to *Arthrobacter nicotinovorans* and 96.9% to *Arthrobacter histidinolovorans*. The peptidoglycan structure of *Arthrobacter alkaliphilus* (Lys–Ser–Thr–Ala) and the quinone system of MK-9(H_2) with significant amounts of MK-10(H_2) distinguishes it from *Arthrobacter methylotrophicus*, which contains Lys–$Ala_{2–4}$ and MK-9(H_2) but no MK-10(H_2). *Arthrobacter nicotinovorans* and *Arthrobacter histidinolovorans* are also distinguishable from *Arthrobacter alkaliphilus* based on peptidoglycan structure and quinone system. The peptidoglycan structure of *Arthrobacter alkaliphilus* is characteristically that of "*Arthrobacter oxydans* group", and hence *Arthrobacter alkaliphilus* is tentatively placed in this group.

Phylogenetic analyses of the rRNA genes of *Arthrobacter crystallopoietes* do not yield a stable assignment to any phylogenetic subclade. It shares 97.6% 16S rRNA gene similarity with the type species of the genus, *Arthrobacter globiformis*, and no other species possesses higher similarity. Sequence similarity values with other species of "*Arthrobacter globiformis* group" (*Arthrobacter sensu stricto*; rRNA cluster 1) are in the range of 96.2–97.1%. The peptidoglycan interpeptide bridge consists of Lys–Ala, which is similar to that of other rRNA cluster 1 species. The cell-wall sugars Gal and Glc are also found in other species of this group. Hence, *Arthrobacter cyrystallopoietes* is tentatively placed in "*Arthrobacter globiformis* group".

Arthrobacter nasiphocea possesses low 16S rRNA gene similarity, 95.5–96.5%, with *Arthrobacter woluwensis*, *Arthrobacter pascens*, *Citricoccus alkalitolerans*, *Arthrobacter oryzae*, *Arthrobacter methylotrophus*, *Arthrobacter nitroguajacolicus*; *Arthrobacter phenanthrenivorans*, *Arthrobacter roseus*, *Arthrobacter humicola*, *Arthrobacter oxydans*, and *Arthrobacter polychromogenes*. Likewise, phylogenetic analyses do not suggest a clear affiliation with any of the *Arthrobacter* groups. The unrelatedness of *Arthrobacter nasiphocea* to other *Arthrobacter* species is also indicated from the peptidoglycan structure (Lys–Ala_2-$Gly_{2–3}$–Ala [Gly]) and quinone system MK-9(H_2) + MK-8(H_2). Hence, *Arthrobacter nasiphocea* might be considered a representative of a novel genus. Table 96 lists differential phenotypic characteristics for this species relative to some other ungrouped species.

In both maximum likelihood and neighbor-joining phylogenetic analyses of the16S rRNA gene, *Arthrobacter methylotrophus* is associated with *Arthrobacter alcaliphilus* but without bootstrap support. The 16S rRNA gene sequences of these two species share 97.4% similarity, but similarities with certain species of "*Arthrobacter globiformis* group", "*Arthrobacter aurescens* group", "*Arthrobacter oxydans* group", and "*Arthrobacter agilis* group" are not much lower, 96.9–97.3%. Hence, 16S rRNA data do not unambiguously indicate an affiliation of *Arthrobacter methylotrophus* to any specific *Arthrobacter* group. It contains the menaquinone MK-9(H_2), which is widely distributed in arthrobacters and not helpful for classification of this species. The peptidoglycan interpeptide bridge is $Ala_{2–4}$ and also similar to those found in

TABLE 76. The "*Arthrobacter oxydans* group" (rRNA cluster 3), including tentatively assigned species *Arthrobacter alkaliphilus*[a,b,c]

[g]Negative in Osorio et al. (1999).

other groups, including representatives of the "*Arthrobacter globiformis* group", "*Arthrobacter pigmenti* group", and "*Arthrobacter psychrolactophilus* group". Since 16S rRNA gene sequence similarities with species of the latter two groups are significantly lower, *Arthrobacter methylotrophus* is tentatively assigned to the "*Arthrobacter globiformis* group".

Arthrobacter ramosus exhibits 16S rRNA gene similarities of 97.2–98.2% with species of the "*Arthrobacter aurescens* group", but phylogenetic analyses do not provide support for this or any other affiliation (Figure 137). The peptidoglycan interpeptide bridge of Lys–Ala_4 is also not consistent with an association with the "*Arthrobacter aurescens* group", whose members possess Lys–Ala–Thr–Ala. Sequence similarities with species of "*Arthrobacter globiformis* group" and *Arthrobacter methylotrophicus* are in the range of 96.3–96.8% and 96.3–97.1%, respectively, which also does not support a clear affiliation to these groups. Nevertheless, based on moderate sequence similarities and a similar peptidoglycan interpeptide bridge, *Arthrobacter ramosus* is tentatively placed in the "*Arthrobacter globiformis* group".

In some phylogenetic trees, *Arthrobacter roseus* is placed at the root of the "*Arthrobacter psychrolactophilus* group" but without bootstrap support for assignment to this group. High 16S rRNA gene similarities of 97.0–97.6% identify the "*Arthrobacter oxydans* group" as the next closest relatives. However, the composition of its peptidoglycan interpeptide bridge, Lys–Gly–Ala_3, is unique within *Arthrobacter* and does not provide clear evidence for an assignment to any of the designated *Arthrobacter* groups. Likewise, the menaquinone is MK-9(H_2), which is common within the genus. Hence, this species may be a representative of a novel genus within the *Micrococcaceae*. Table 96 lists differential phenotypic characteristics for this species relative to some other ungrouped species.

Phylogenetic analyses suggest that *Arthrobacter russicus* is closely related to *Renibacterium salmoninarum*, a relationship that is also supported by a high 16S rRNA gene similarity of 97.2%. However, these species differ significantly in G+C content (65.5 and 56.3 mol%, respectively; Li et al., 2004c; Wiens et al., 2008); in the quinone system, and in peptidoglycan structure. *Arthrobacter russicus* has menaquinone MK-9(H_2) and a peptidoglycan with Lys–Ala_2, whereas *Renibacterium salmoninarum* has MK-9 and peptidoglycan with Lys–Ala–Gly (Kusser and Fiedler, 1983; Sanders and Fryer, 1980). These differences may

be explained by the evolution of *Renibacterium salmoninarum* from an *Arthrobacter*-like ancestor, largely via genome reduction (Wiens et al., 2008), adaption to the salmonid host, and loss of some biosynthetic capabilities. Nevertheless, the absence of significant phenotypic similarities does not support the reclassification of *Arthrobacter russicus* within the genus *Renibacterium*. Compared to *Arthrobacter globiformis*, the 16S rRNA gene of *Arthrobacter russicus* possesses a 12-bp insertion (position 421–432), which is also found in *Renibacterium salmoninarum* and other moderately related *Arthrobacter* species, such as *Arthrobacter psychrolactophilus* (95.5% 16S rRNA gene sequence similarity), *Arthrobacter stackebrandtii* (95.4% 16S rRNA gene sequence similarity), and *Arthrobacter agilis* (94.9% 16S rRNA gene sequence similarity). In other species, such as *Arthrobacter pigmenti*, *Arthrobacter castelli*, *Arthrobacter albus*, and *Arthrobacter cumminsii*, the insertion at this position is a few nucleotides shorter. Whereas peptidoglycan structures clearly distinguish *Arthrobacter russicus* from *Arthrobacter psychrolactophilus* and *Arthrobacter agilis*, no differences in this trait were reported for *Arthrobacter russicus* and *Arthrobacter stackebrandtii*. In sequence comparisons where this insertion is removed from the 16S rRNA gene sequence, *Arthrobacter globiformis* is among the species sharing highest similarities (>96.0%). Since *Arthrobacter russicus* branches in phylogenetic trees which do not include *Renibacterium salmoninarum* at the root of the "*Arthrobacter psychrolactophilus* group" (Ding et al., 2009; Pindi et al., 2010; Tvrzová et al., 2005b; Zhang et al., 2010) and shares with *Arthrobacter stackebrandtii* the peptidoglycan type (Lys–Ala_2) and the quinone system MK-9(H_2), this species is tentatively placed in "*Arthrobacter psychrolactophilus* group".

Arthrobacter sanguinis shares 16S rRNA gene similarities of 94.0–95.2% with *Arthrobacter* species from different *Arthrobacter* groups, such as *Arthrobacter crystallopoietes*, *Arthrobacter cumminsii*, *Arthrobacter globiformis*, *Arthrobacter phenanthrenivorans*, *Arthrobacter pascens*, *Arthrobacter albus*, and *Arthrobacter bergerei* but also with the type strain of *Kocuria rosea*. Phylogenetically, *Arthrobacter sanguinis* forms a separate line of descent with *Acaricomes phytoseiuli*, but this clade is not supported by high bootstrap values, and the two species share only 93.9% 16S rRNA gene similarity. Although it is obvious from these data that *Arthrobacter sanguinis* is not a member of *Arthrobacter sensu stricto* or any of the other *Arthrobacter* groups described herein, it is not placed in a new group because important information is not available, including both the quinone system and peptidoglycan structure. If chemotaxonomic data were available, it might support classification with *Acaricomes phytoseiuli* in the genus *Acaricomes* or placement in a novel genus. Table 96 lists

[c]Predominant.

differential phenotypic characteristics for this species relative to some other ungrouped species.

Among species of the genus *Arthrobacter*, *Arthrobacter woluwensis* is the only species with Asp in the peptidoglycan interpeptide bridge, which is designated peptidoglycan type A4α (Schleifer and Kandler, 1972) or A11.31 (http://www.peptidoglycan-types.info). Other *Arthrobacter* species with an A4α type interpeptide bridge possess Glu alone (A11.33), Ala–Glu (A11.35), or Ala–Ser–Glu (A11.38, A11.48, or A11.58). Sequence similarities of 96.7–97.6% in the 16S rRNA gene suggest that this species is a relative of the *Arthrobacter globiformis* group, but there is no bootstrap support for this assignment. Three species of the *Arthrobacter nicotianae* group, two species of *Arthrobacter oxydans* group, and *Arthrobacter methylotrophus*, *Arthrobacter crystallopoietes*, *Arthrobacter roseus*, and *Arthrobacter alkaliphilus* also possess similarity values within this range or slightly lower, 96.4–96.8%. In the absence of a clear assignment to a subclade one rRNA cluster, the unique peptidoglycan of *Arthrobacter woluwensis* suggests that it represents a novel genus, and hence it is not assigned to any of the other *Arthrobacter* groups. Table 96 lists differential phenotypic characteristics for this species relative to some other ungrouped species.

Degradation potential. Numerous arthrobacters have been examined for their potential to degrade xenobiotics and other harmful substances.

Three *Arthrobacter* strains isolated from soil surrounding an outdoor coal storage pile grew with naphthalene vapor as sole source of carbon. However, none of the known genes for naphthalene degradation were detected, such as *nahAc*, *nahAd*, *nahH*, *phnAC*, *xzlE*, or *GST* (Dore et al., 2003). Several phenanthrene-degrading *Arthrobacter* strains have been isolated after long-term exposure to the polycyclic aromatic hydrocarbons (Bodour et al., 2003).

Arthrobacter aurescens TC1 metabolizes 23 different *s*-triazine compounds including atrazine, which it utilizes as a sole source of carbon and nitrogen. Catabolic enzymes involved are TrzN, AtzB, and AtzC (Sajjaphan et al., 2004; Strong et al., 2002). The amidohydrolase TrzN is a zinc-containing enzyme that has a broader specificity than AtzA, the corresponding enzyme of *Pseudomonas* sp. strain ADP and displaces cyano, azido, halide, S-alkyl, and O-alkyl substituents (Shapir et al., 2006; Strong et al., 2002). Further studies suggest that the genes *trzN*, *atzB*, and *atzC* are located on a 380-kb plasmid (Sajjaphan et al., 2004). Another atrazine degrader, *Arthrobacter* AD1 is very closely related to *Arthrobacter ureafaciens* on the basis of 16S rRNA gene similarity. Its *atzA* gene is located on the chromosome (Cai et al., 2003). Three atrazine-degrading strains closely related to *Arthrobacter crystallopoietes* were isolated from French soil (Rousseaux et al., 2001), and the catabolic genes were located on a 117-kb plasmid (Rousseaux et al., 2002).

Degradation of 4-chlorophenol has been reported for several arthrobacters. *Arthrobacter ureafaciens* CPR706 first eliminates the chloro-substituent to form hydroquinone. This strain also degrades other *para*-substituted phenols, including 4-nitro-, 4-bromo-, 4-iodo-, and 4-fluorophenol via the hydroquinone pathway. It does not degrade *ortho*- or *meta*-substituted phenols (Bae et al., 1996). The type strain of *Arthrobacter defluvii* and a second strain of this species were isolated by Kim et al. (2008) after stimulation of a sewage sample with 4-chlorophenol. Another *Arthrobacter* strain, described as *Arthrobacter chlorophenolicus* (Westerberg et al., 2000) was isolated after successively increasing the 4-chlorophenol concentration in a soil suspension from 50 to 350 p.p.m. over a period of 165 d. Two strains of *Arthrobacter nitroguajacolicus* were enriched from forest soil and shown to degrade 4-nitroguaiacol. A third strain of this species produces 4-nitroguaiacol in the course of 4-nitrophenol transformation (Kotoučková et al., 2004).

Arthrobacter sp. strain SU DSM 20407 hydrolytically dehalogenates 4-chlorobenzoate, a breakdown product of polychlorinated biphenyls. The degradation requires three genes organized in an operon on the plasmid pASU1. These genes, designated *fchA*, *fchB*, and *fchC*, encode 4-chlorobenzoate:CoA ligase, 4-chlorobenzoyl-CoA dehalogenase, and 4-hydroxybenzoyl-CoA thioesterase (Schmitz et al., 1992; Zhuang et al., 2003). The same set of genes is also present in *Arthrobacter* sp. strain TM-1, which was originally isolated from sewage sludge by enrichment on 4-chlorobenzoate. *Arthrobacter* sp. strain TM-1 dehalogenates 4-chlorobenzoate, and the product, 4-hydroxybenzoate, is further metabolized via protocatechuate. However, other chlorinated benzoates as well as benzoate itself do not support growth and are presumably not metabolized (Marks et al., 1984). The first enzyme in the pathway, 4-chlorobenzoate:CoA ligase produces 4-chlorobenzoyl CoA and AMP (Zhou et al., 2004). The second enzyme is a trimeric protein, 4-chlorobenzoyl CoA dehalogenase, and has a secondary and three-dimensional structure similar to that of the corresponding enzyme from *Pseudomonas* sp. CBS-3. Dehalogenase activity in *Arthrobacter* sp. strain TM-1 is also inhibited by dissolved oxygen and stimulated by manganese (Zhou et al., 2008b).

Cullington and Walker (1999) isolated a bacterial strain D47 capable of degrading the substituted phenylurea herbicides diuron, isoproturon, chlorotoluron, linuron, monolinuron, and monuron. Turnbull et al. (2001) showed that this strain is closely related to *Arthrobacter oxydans* and *Arthrobacter polychromogenes* and that it hydrolyzes the urea side chain at the carbonyl group. *Arthrobacter* RC100 contains three plasmids, and two of them are involved in mineralization of carbaryl (1-naphthyl *N*-methylcarbamate), which is one of the most commonly used carbamate pesticides for the control of a wide variety of insects. During the mineralization, metabolites that appear early in the suspension are 1-naphthol and salicylic acid. *Arthrobacter* sp. RC100 grows also on salicylic acid, 1-naphthol, gentisic acid, protocatechuic acid, salicylaldehyde, and 2-naphthol (Hayatsu et al., 1999).

The *N*-heteroaromatic quinaldine (2-methylquinoline) is utilized by *Arthrobacter nitroguajacolicus* Rü61a (formerly assigned to the species *Arthrobacter ilicis*) as a source of carbon, nitrogen, and energy. The degradation proceeds via the "anthranilate pathway" (Parschat et al., 2003). The genes for conversion of quinaldine to anthranilate are located on a the conjugative linear catabolic plasmid pAL1, which comprises 112,992 bp (Parschat et al., 2007).

Arthrobacter protophormiae RKJ100 utilizes *o*-nitrobenzoate as sole source of carbon, nitrogen, and energy via an oxygen insensitive pathway that releases ammonia to the culture medium. The catabolic genes are located on a 65-kb plasmid (Chauhan and Jain, 2000). The strain degrades *o*-nitrobenzoate via a reductive pathway leading to the formation of *o*-hydroxylaminobenzoate and anthranilate (Pandey et al., 2003). Also *p*-nitrophenol and 4-nitrocatechol are degraded by *Arthrobacter protophormiae* RKJ100, and the corresponding genes are encoded from the same 65-kb plasmid (Chauhan et al., 2000).

"*Arthrobacter keyseri*" 12B (originally designated *Micrococcus* strain 12B) possesses high 16S rRNA gene similarity to *Arthrobacter ureafaciens*, but the name has never been validly published and hence it does not have standing in nomenclature. The strain converts phthalate to protocatechuate through *cis*-3,4-dihydroxy-3,4-dihydrophthalate and 3,4-dihydroxyphthalate. The genes of the catabolic pathway are plasmid encoded, and sequence analysis reveals genes encoding a transposon resolvase, enzymes required for catabolism of protocatechuate (3,4-dihydroxybenzoate), a putative ATP-binding cassette transporter, a possible phthalate ester hydrolase, a fragment of a norfloxacin resistance-like transporter, and enzymes required for the conversion of phthalate to protocatechuate, respectively (Eaton, 2001).

Arthrobacter sp. strain JBH1 was isolated after enrichment from a nitroglycerin-contaminated site, and it can grow with nitroglycerin as sole source of carbon, nitrogen, and energy. The strain shares 99.5% 16S rRNA gene similarity with *Arthrobacter pascens*, indicating that it is a representative of the genus *Arthrobacter sensu stricto*. It converts nitroglycerin via 1,2-dinitroglycerin to glycerin, which serves as an energy source (Husserl et al., 2010).

Arthrobacter nicotinovorans has the ability to use the tobacco plant alkaloid nicotine as its sole source of carbon and energy. The catabolic genes are located on the 165-kb plasmid pAO1, which also confers the ability to take up nicotine from the medium (Baitsch et al., 2001; Igloi and Brandsch, 2003). Furthermore, the plasmid encodes enzymes essential for biosynthesis of the molybdenum dinucleotide cofactor of nicotine dehydrogenase as well as open reading frames necessary for the uptake and utilization of carbohydrates, sarcosine, and amino acids. pAO1 was successfully transferred by conjugation to a pAO1-negative strain, so genes for conjugation must be present as well.

Enzymes. While a number of enzymes have been identified and characterized in arthrobacters, many are from strains whose identifications are ambiguous. Many of these strains are assigned to the genus *Arthrobacter* on the basis of rod–coccus morphological cycle, presence of lysine in the peptidoglycan, fatty acid profile, and/or 16S rRNA analyses. Since these phenotypic traits are not restricted to arthrobacters and the 16S rRNA gene analysis is sometimes misleading, it is likely that in the future some of the *Arthrobacter* strains listed below will be assigned to other genera.

A strain of *Arthrobacter ilicis* associated with the marine sponge *Spirastrella* sp. produces an extracellular serine type acetylcholinesterase with maximum activity at 45°C and pH 8.0 (Mohapatra and Bapuji, 1998). The enzyme activity is unaffected by Mg^{2+} and Ca^{2+} but inhibited by higher concentrations (25 mM) Co^{2+}, Cu^{2+}, Hg^{2+}, Mn^{2+}, Ni^{2+} and Zn^{2+} as well as EDTA.

Arthrobacter FR-3, isolated from sediment samples of a swamp near the Dow's Lake, Ottawa, Canada, produces a serine-type sulfide oxidase. The free and immobilized sulfide oxidase shows optimal activity at pH 7.5 and 6.0, respectively, and at 35°C. Enzyme activity is not inhibited by 1 mM Ca^{2+}, Mg^{2+}, Na^{+}, and EDTA, but it is completely inhibited by 1 mM Co^{2+} and Zn^{2+} (Mohapatra et al., 2006).

The psychrophilic *Arthrobacter* sp. strain TAD20 produces two cold-adapted, heat labile chitinases, *Ar*ChiA and *Ar*ChiB. The chitinases are active at 4°C but not at 17 or 24°C. They lose 50–60% activity after incubation at 50°C for 30 min. Deduced from the gene sequences, the primary structures of *Ar*ChiA and *Ar*ChiB consist of 846 and 539 amino acids, respectively. Metals are not required for activity, and their activity is unaffected by 10 mM EDTA (Lonhienne et al., 2001).

Three different β-galactosidases have been detected in *Arthrobacter* B7. The sizes of the isozymes are 111 kDa, 71 kDa, and 52 kDa. The 111-kDa isozyme exhibits 22% amino acid sequence similarity with the EbgA protein of *Escherichia coli*, but the optimum temperature is approximately 20°C lower than that of the *Escherichia coli* β-galactosidase. The enzyme requires Mn^{2+} or Mg^{2+} at 1 mM for maximum activity; Ca^{2+} supports 61% activity, whereas Cu^{2+} is completely inhibitory (Trimbur et al., 1994). The amino acid sequence of the 71-kDa isozyme (designated group *lacG*) has little similarity with the enzymes of the *lacZ* family. Highest similarity was found with β-galactosidases from endospore-formers, such as the thermophile *Geobacillus stearothermophilus* (21.8%) and *Bacillus circulans* (17.7%). The enzyme is active over a pH range from 6 to 9 and activity is optimum at pH 6.8. The enzyme activity is reduced after treatment with EDTA but can be restored by addition of 5 mM Mg^{2+}, 10 mM Mn^{2+}, or Ca^{2+}; 10 mM Co^{2+} also increases the activity whereas Ni^{2+} has no effect and Cu^{2+} is inhibitory. The activity is optimal at 45–50°C and is quite stable for at least 70 h at 25, 30, and 35°C (Gutshall et al., 1995). The 52-kDa β-galactosidase of *Arthrobacter* B7 is active as a dimer and hydrolyzes β-1,4 or β-1,3 glycoside linkages. The amino acid sequence is most similar to human and mouse acid β-galactosidase and a corresponding enzyme of *Xanthomonas manihotis* (Gutshall et al., 1997).

The psychrophile *Arthrobacter* strain SB from the Antarctic is a close relative of *Arthrobacter sulfonivorans*. The strain produces a β-galactosidase (BgaS) which exhibits optimal activity at 18°C, 50% activity at 0°C, but is inactivated within 10 min at 37°C. At 4°C, the active enzyme is a homotetramer but dissociates into inactive monomers at 25°C. After dissociation into monomers, the enzyme does not regain activity even when cooled to 4°C. The size of the monomer is approximately 116 kDa. The enzyme is active from pH 6.0 to 9.5, with greatest activity at pH 7.0. Activity is dependent on Mg^{2+}, whereas other mono- or divalent cations have only small stimulatory effects. EDTA inactivates the enzyme at a concentration of 100 mM within 90 min. The nucleotide sequence of the gene that encodes BgaS has highest similarity with those of *lacZ*-like genes of *Arthrobacter* sp. C2-2 and *Arthrobacter psychrolactophilus* (Coker et al., 2003). A cold-adapted β-galactosidase was also characterized from another Antarctic strain, *Arthrobacter* sp. 32c (Hildebrandt et al., 2009). This strain is a close relative of *Arthrobacter oxidans* and *Arthrobacter polychromogenes*. The gene sequence of the enzyme has highest similarity with those of *Arthrobacter* FB24 (77.1%) and *Arthrobacter aurescens* TC1 (71.8%). The enzyme has a temperature optimum at 50°C, with residual activity being 60% at 25°C, and 15% at 0°C. The pH optimum is 6.5, but more than 90% activity remains at pH 8.5. Treatment with 100 mM EDTA for 2 h does not affect the activity. Metal ions such as Na^{+}, K^{+}, Mg^{2+}, Co^{2+}, or Ca^{2+} do not affect activity, whereas Mn^{2+}, Fe^{2+}, and Ni^{2+} strongly and Cu^{2+} or Zn^{2+} completely inhibit the enzyme.

Arthrobacter D10, which was isolated from soil in Pennsylvania, produces an extracellular alkaline phosphatase (de Prada et al., 1996). At pH 9.1, the activity is maximal at 45–50°C. Further examination demonstrated two extracellular alkaline phosphatases, designated D10A and D10B. Alkaline phosphatase

D10B requires calcium for optimal activity, whereas D10A has equal activity with or without calcium. D10A has a maximum pH around 9.5 and is active in the pH range 7.0–11.0. D10B has a narrower pH range, with a maximum at pH 9.0 and less than 10% activity at pH 7.0 and 9.5. D10A loses 60% of activity within 15 min at 55°C, and the less heat-labile D10B loses 20% of activity within 15 min at 55°C.

The soil isolate *Arthrobacter* strain KM possesses activities for several inorganic polyphosphate [poly(P)]- and ATP-dependent kinases including glucokinase, NAD kinase, mannokinase, and fructokinase (Mukai et al., 2003). An enzyme purified from this strain phosphorylates glucose and mannose utilizing either poly(P) or ATP and was designated poly(P)/ATP-glucomannokinase. The enzyme is a monomer with a molecular mass of approximately 30 kDa. The corresponding gene consists of 804 bp. The enzyme has highest activity at pH 7.5 and 45°C, but 50% activity is lost after treatment at 40°C for 5 min. Both enzyme functions, poly(P)- and ATP-dependent gluco- and mannokinase activities require Mg^{2+} or Mn^{2+}. Zn^{2+} and Co^{2+} mediate high activity only for poly(P)-dependent glucomannokinase activity (Mukai et al., 2003).

A pyridoxal-5′-phosphate-dependent D-threonine aldolase has been purified and characterized from *Arthrobacter* sp. DK-38 (Kataoka et al., 1997). The 51-kDa enzyme catalyzes cleavage of D-threonine into glycine and acetaldehyde and the reverse reaction forming D-threonine and D-allothreonine. It is inhibited by chelating reagents such as EDTA, and activity is dependent on divalent cationic salts, including $MnCl_2$, $MgCl_2$, $CoCl_2$, $NiCl_2$, and to a lesser degree $FeSO_4$, whereas $CaCl_2$ has little effect. Other metallic salts including $CuSO_4$, $ZnSO_4$, NaCl, KCl, $AlCl_2$, and $FeCl_2$ have no effect, and Ag_2SO_4, $HgCl_2$, and $CdCl_2$ completely inhibit the enzyme activity. $MnCl_2$ also contributes significantly to thermal stability of the enzyme (Kataoka et al., 1997).

Two extracellular proteinases and an extracellular proline iminopeptidase have been characterized from *Arthrobacter nicotianae* 9458, isolated from the bacterial smear of surface ripened cheeses (Smacchi et al., 1999a, 1999b). The proteinases have molecular masses of approximately 54 kDa (proteinase P1) and 71 kDa (proteinase P2). Both proteinases degrade α_{s1}- and β-casein rapidly at pH 6.5 and 37°C. The optima of the two enzymes are pH 9.5 and 9.0, respectively, but both are still active at pH 6.5. At their optimal pH, the temperature optima are 37°C and 55–60°C, respectively, and both enzymes remain active at 15°C. P1 is irreversibly inactivated after exposure to 70°C for 1 min. The second proteinase, P2, retains 50% of its activity under the same conditions but is inactivated at 85°C after 1 min. EDTA has a strong inhibitory effect on P1 but is only moderately inhibitory to P2. Both enzymes are inhibited by 1 mM Zn^{2+}, Hg^{2+}, Ni^{2+}, Cu^{2+}, or Co^{2+}. At higher concentrations, Fe^{2+} and Mn^{2+} are inhibitory as well. The proline iminopeptidase has a molecular mass of about 54 kDa. Its temperature optimum is 37°C, but activity decreases rapidly above 42°C. Its pH optimum is at 8.0, but 60% of the maximal activity is retained at pH 9.0. It is completely inhibited after treatment for 1 min at 80°C. EDTA is moderately inhibitory. Fe^{2+} and Sn^{2+} completely inactivate the enzyme, and only a little activity is observed in the presence of Zn^{2+}, Hg^{2+}, Ni^{2+}, Cu^{2+}, or Co^{2+}. Mn^{2+} is moderately inhibitory, and Ca^{2+} and Mg^{2+} have little effect.

Genes for degradation of creatinine to glycine and formaldehyde have been identified in *Arthrobacter* sp. TE1826. Together with the repressor gene *soxR*, the *soxA*, *crnA*, and *creA* genes are organized in an operon. The *crnA* gene encodes a 258-amino acid protein, and the *creA* gene encodes a 441-amino acid protein (Nishiya et al., 1998).

A gene encoding a dimethylglycine dehydrogenase (*dmg*) has been identified in *Arthrobacter globiformis* NRRL-B2979, and *soxBDAG* genes encoding the subunits of the heterotetrameric sarcosine oxidase have been identified in *Arthrobacter* spp. 1-IN (Meskys et al., 2001). The *dmg* gene encodes a protein of 830 amino acids whose molecular mass is approximately 90 kDa.

Enrichment and isolation procedures

Due to the high number of species within the genus and their different physiological properties, no general procedure for enrichment and isolation can be recommended. The majority of *Arthrobacter* species are unexacting and grow on standard media containing peptone and yeast extract at or near neutral pH, such as nutrient broth or trypticase soy broth. As shown by Funke et al. (1996), who examined the antibiotic sensitivity of 24 *Arthrobacter* strains, resistance to ciprofloxacin, clindamycin, and gentamicin is widespread among this genus. Hence, supplementation of the enrichment and isolation medium with these antibiotics may be suitable.

Maintenance procedures

Standard procedures for conservation are recommended, such as storage of culture in 25% glycerol at −80°C or lyophilization.

List of species of the genus *Arthrobacter*

1. **Arthrobacter globiformis** (Conn 1928) Conn and Dimmick 1947, 301[AL] (Basonym: *Bacterium globiforme* Conn 1928, 3.)

glo.bi.for′mis. L. n. *globus* ball, globe; L. adj. suff. *-formis -is -e* (from L. n. *forma* figure, shape, appearance) -like, in the shape of; N.L. masc. adj. *globiformis* spherical.

Nonmotile. Colonies on yeast extract-peptone media show no distinctive pigmentation. Either nutritionally nonexacting or require biotin alone. Growth occurs in a suitable mineral salts medium with an ammonium salt or nitrate as sole nitrogen source (with biotin if required) and with glucose as carbon + energy source. The widely used Conn strain ATCC 4336 (NCIB 8602) requires biotin; the type strain does not. Starch is hydrolyzed, nicotine is not utilized. The cell-wall peptidoglycan is of the Lys–Ala_3 type, A3α (Fiedler et al., 1970). The whole-cell sugars are galactose and glucose. The principal isoprenoid quinone is MK-9(H_2) (Collins et al., 1979). The predominant fatty acid is $C_{15:0}$ anteiso (48%), followed by $C_{15:0}$ iso (21%), $C_{17:0}$ anteiso (7%), $C_{16:0}$ iso (7%), $C_{16:0}$ (4%), $C_{14:0}$ iso (2%), and $C_{17:0}$ iso (2%). All other fatty acids are at levels below 1% (Funke et al., 1996).

DNA G+C content (mol%): 62.0–65.5 (T_m).

Type strain: AS 1.1894, ATCC 8010, BCRC (formerly CCRC) 10598, CCUG 581, CCUG 12157, CCUG 28997, CIP 81.84, DSM 20124, HAMBI 88, HAMBI 1863, IAM 12438, ICPB 3434, NBRC 12137, JCM 1332, LMG 3813, NCIMB 8907, NRIC 0151, NRRL B-2979, VKM Ac-1112.

Sequence accession no. (16S rRNA gene): X80736.

Sequence accession no. (recA): AF214780

Additional remarks: after continuously decreasing oxygen tension in the growth medium, the type strain of *Arthrobacter globiformis* is able to grow in the presence of nitrate, glucose and pyruvate as carbon sources carrying out anaerobic respiratory nitrate reduction with fermentation of carbon sources and also to grow anaerobically in the absence of nitrate, with glucose and pyruvic acid as carbon sources (Eschbach et al., 2003).

2. **Arthrobacter agilis** (Ali-Cohen 1889) Koch, Schumann and Stackebrandt 1995, 837[VP] (*Micrococcus agilis* Ali-Cohen 1889, 36)

a′gi.lis. L. masc. adj. *agilis* agile.

Spheres (0.8–1.2 μm in diameter) occur in pairs and tetrads. Agar colonies are circular, entire, slightly convex, smooth, and matte. Sediment is formed in nutrient broth. No growth occurs on Simmons' citrate medium. Good growth and dark rose-red pigmentation occur on agar slants. The pigment is water insoluble. Motile by means of one to three flagella. Nonmotile strains may occur. Spores are not formed. Gram-stain-positive. The cell-wall peptidoglycan type is type L-Lys–L-Thr–L-Ala (variation A3α). The predominant menaquinone isoprenologue is MK-9(H_2); MK-8(H_2) is a minor component. Contains major amounts of anteiso methyl-branched acids (~65.5% $C_{15:0}$ anteiso) and smaller amounts of iso methyl-branched acids (~13% $C_{15:0}$ iso and ~6% $C_{16:1}$ iso). The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and an unknown ninhydrin-negative glycolipid. The amino sugar in the cell-wall polysaccharide is glucosamine. Chemo-organotrophic. Metabolism is respiratory. Aerobic. Acid and gas are not produced from glucose, mannose, lactose, galactose, and glycerol. Catalase-positive. Porphyrin respiratory enzymes are produced. Oxidase-positive. Acetylmethylcarbinol is not produced. β-Galactosidase (*o*-nitrophenyl-β-D-galactopyranoside test) positive. Methyl red negative. Indole and hydrogen sulfide are not produced. Nitrate is not reduced. Gelatin, starch, and esculin are hydrolyzed. Arginine dihydrolase, ornithine and lysine decarboxylases, and phenylalanine deaminase are not produced. Tween 80 may be split. DNase may be produced. Urease, tyrosinase, and phosphatase are not produced. Beta-hemolysis does not occur. Good growth occurs at temperatures between 20 and 30°C. No growth occurs at 37°C. No growth occurs on medium containing 5% NaCl. Susceptible to penicillin, streptomycin, chloramphenicol, tetracycline, erythromycin, novobiocin, ampicillin, carbenicillin, and gentamicin. Resistant to lysozyme. Saprophytic.

Type strain: ATCC 966, DSM 20550, CCM 2390, CIP 81.67, NBRC 15319, JCM 2584, LMG 17244, VKM B-1973.

Sequence accession no. (16S rRNA gene): X80748.

Sequence accession no. (recA): AF214779

3. **Arthrobacter albidus** Ding, Hirose and Yokota 2009, 860[VP]

al′bi.dus. L. masc. adj. *albidus* whitish, referring to the color of the colonies.

Cells are nonmotile and non-spore-forming. Gram-stain positive, catalase-positive, oxidase-negative. Shows a rod–coccus growth cycle and produces non-fluorescent pigment. Growth occurs on nutrient broth agar at 10–40°C, optimal temperature for growth is 30°C. Grows in the presence of 3–7% (w/v) NaCl, but no growth occurs in the presence of 7% NaCl. The pH range for growth is 6–10, and the optimum pH is 7. Colonies are round, convex, glossy, with entire margins and are white or light yellow. Using the API CORYNE system, positive reactions are observed for activities of pyrazinamidase, pyrrolidonyl arylamidase, and urease and for the utilization of ribose and mannitol. Negative reactions are obtained for nitrate reduction, hydrolysis of gelatin, and for the utilization of maltose, lactose, and glycogen. Utilization of glucose, xylose, and sucrose is weak. Using the API ZYM system, activity is detected for alkaline phosphatase, esterase lipase C8, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, and α-mannosidase. No activity is detected for lipase C14, achymotrypsin, α-galactosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. Esterase C4 and acid phosphatase activities are weak. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{15:0}$ iso. The diagnostic diamino acid of the cell-wall peptidoglycan is lysine and the major components are lysine, serine, and alanine. The menaquinone composition is MK-9(H_2) (83%), MK-10(H_2) (14%), and MK-8(H_4) (2%).

Source: a filtration substrate made from volcanic rock from Niigata, Japan.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: LC13, CCTCC 206018, IAM 15386, JCM 21830.

Sequence accession no. (16S rRNA gene): AB248533.

4. **Arthrobacter albus** Wauters, Charlier, Janssens and Delmée 2000b, 1699[VP] (Effective publication: Wauters, Charlier, Janssens and Delmée 2000a, 2415.)

al′bus. L. masc. adj. *albus* white, because of the white colonies of the organism.

Cells are small coryneform bacteria, nonmotile and without spore formation. Colonies are white and are 1 mm in diameter after 48 h of incubation at 37°C on blood agar. Metabolism is obligately aerobic. Catalase is positive. Urease and esculin are not hydrolyzed, and nitrates are not reduced. Gelatin is slowly and weakly liquefied, and there is no DNase activity. Tyrosine is not hydrolyzed. Simmons' citrate is negative. Pyrrolidonyl peptidase is positive. The organism is resistant to desferrioxamine. No acid is produced from carbohydrates, and there is no utilization of these substrates in the API 50 CH system. Alkaline and acid phosphatase, phosphoamidase, esterase, esterase-lipase, leucine arylamidase, and trypsin are present but not lipase, valine arylamidase, cystine arylamidase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetylglucosaminidase, α-mannosidase, and α-fucosidase. The main cellular fatty acid is $C_{15:0}$ anteiso, and the peptido-

glycan type is L-Lys–L-Ala–L-Glu.

Source: human clinical specimens.

DNA G+C content (mol%): not determined.

Type strain: CF-43, DSM 13068, ATCC BAA-273, CCUG 43812, CIP 106791, JCM 11943.

Sequence accession no. (16S rRNA gene): AJ243421.

5. **Arthrobacter alkaliphilus** Ding, Hirose and Yokota 2009, 859[VP]

al.ka.li′phi.lus. N.L. n. *alkali* (from the Arabic word al-qaliy) the ashes of saltwort; Gr. adj. *philos* loving; N.L. masc. adj. *alkaliphilus* loving alkaline environments.

Cells are nonmotile and non-spore-forming. Gram-stain positive, catalase-positive, and oxidase-negative. Shows a rod–coccus growth cycle and produces non-fluorescent pigment. Growth occurs on nutrient broth agar at 5–40°C, optimal temperature for growth is 30°C. Grows in the presence of 3–7% (w/v) NaCl. The pH range for growth is 6–11 and the optimum pH is 8.5. Colonies are round, convex, glossy, with entire margins and are light yellow. Using the API CORYNE system, positive for pyrazinamidase, pyrrolidonyl arylamidase, and urease activity and for glucose, ribose, maltose, and mannitol utilization. Negative reactions are obtained for nitrate reduction, for hydrolysis of gelatin, and for utilization of glycogen, sucrose, and xylose. Lactose gives a weak reaction. Using the API ZYM system, activity is detected for alkaline phosphatase, acid phosphatase, esterase lipase C8, leucine arylamidase, valine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, and α-mannosidase. No activity is detected for esterase C4, lipase C14, cystine arylamidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. The activity of α-chymotrypsin is weak. Predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. The diamino acid of the cell-wall peptidoglycan is lysine and the major components are lysine, serine, threonine, and alanine. The menaquinone composition is MK-9(H_2) (77%), MK-10(H_2) (17%), and MK-8(H_4) (3%).

6. **Arthrobacter alpinus** Zhang, Schumann, Liu, Xin, Zhou, Schinner and Margesin 2010, 2152[VP]

al.pi′nus. L. masc. adj. *alpinus* alpine inhabitant, referring to the isolation of this strain from an alpine environment.

Cells are irregular rods showing a rod–coccus cycle, 0.8–1.0 × 1.3–1.9 µm after 3 d at 20°C on R2A agar plates, often occurring in pairs as typical V-forms. Cells are Gram-stain-positive, aerobic, and nonmotile. Colonies on R2A agar and on nutrient agar are creamy to yellow 176 after 3 d and yellow after 6 d, round, convex, shiny, and with an entire margin; colony diameter is 1–1.5 mm after 3 d at 20°C on R2A agar. Growth occurs in liquid R2A medium and on agar plates at 1–25°C, with fastest growth rates at 20–25°C; growth is absent at 30°C. On R2A agar plates, growth occurs at pH 6–9 and in the presence of 0–5% (w/v) NaCl. Produces catalase but not cytochrome oxidase. Negative for nitrate reduction, indole production, H_2S production, and citrate utilization. Esculin, urea, and starch are hydrolyzed but not casein and Tween 80. Negative for activities of arginine dihydrolase, lysine dihydrolase, ornithine dihydrolase, lipase (C14), *N*-acetyl-β-glucosaminidase, trypsin, α-chymotrypsin, α-fucosidase, and pyrrolidonyl arylamidase. Positive for activities of alkaline phosphatase, acidic phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, β-glucuronidase, and α-mannosidase. Utilizes D-glucose, lactose, L-arabinose, D-maltose, D-mannose, D-mannitol, and *N*-acetylglucosamine but not citrate, capric acid, adipic acid, and phenylacetic acid as sole carbon source; utilization of Tween 40 is weak. Negative for fermentation of glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, glycogen, inositol, sorbitol, rhamnose, melibiose, amygdalin, and L-arabinose. Sensitive to ampicillin, penicillin G, streptomycin, tetracycline, and chloramphenicol (each 30 µg/ml), but resistant to cyclosporin A (100 µg/ml). The predominant cellular fatty acids of the type strain are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. Contains MK-9(H_2) as the major menaquinone and minor amounts of MK-8(H_2) and MK-10(H_2). The cell-wall peptidoglycan is of the type A3α L-Lys–L-Thr–Ala_3. The predominant cell-wall sugars are galactose and rhamnose.

Source (type strain): an alpine soil in Fuschertörl, Hohe Tauern, Austria.

DNA G+C content (mol%): 61.9 (T_m).

Type strain: S6-3; DSM 22274, CGMCC 1.8950.

Sequence accession no. (16S rRNA gene): GQ227413.

7. **Arthrobacter antarcticus** Pindi, Manorama, Begum and Shivaji 2010, 2265[VP]

an.tarc′ti.cus. L. masc. adj. *antarcticus* southern, used to refer to the Antarctic, referring to the place from where the organism was isolated.

Cells have rod–coccus cycle. Rod-shaped cells grown in tryptone soya broth (TSB) at 22°C for 72 h are 1.5–2.2 µm long and 0.2–0.3 µm wide. Cells are Gram-stain-positive, motile, aerobic, and form a yellow colony on TSB agar plates. Growth occurs between 4–25°C, but not at 30°C; good growth is observed at 22–25°C at pH 7. In TSB agar medium, up to 6% NaCl is tolerated. Cells are positive for catalase, phosphatase, citrate (Simons), lysine and ornithine decarboxylase, and nitrate reduction; but negative for indole production, methyl red, Voges–Proskauer's test, H_2S production, gelatinase, lipase, β- galactosidase, and DNase; hydrolyzes urea and starch but not esculin and casein. Produces acid from D- glucose, sucrose, D-fructose, trehalose, rhamnose, D-arabinose, D-galactose, D-xylose, and inositol, but not from erythritol and D-mannose. Utilizes D-glucose, D-galactose, L-rhamnose, L-arabinose, D-raffinose, trehalose, D-melezitose, salicin, sucrose, adonitol, inulin, sodium acetate, glycine, D- alanine, L-glutamic acid, L-proline, L-serine, L-lysine, and L-arginine as sole carbon source but not D-lactose, maltose, D-melibiose, L-sorbose, glycerol, D- cellobiose, mannitol, D-mannose, dulcitol, D-sorbitol, xylitol, erythritol,

L-isoleucine, L-threonine, L-aspartic acid, L-glutamate, L-asparagine, methionine, L-tyrosine, L-phenylalanine, tryptophan, and L-histidine. Resistant to (in μg/ml) norfloxacin (25), colistin (25), and nitrofurantoin (30), but sensitive to (in μg/ml) kanamycin (15), ampicillin (25), tetracycline (10), streptomycin (20), and rifampin (15). Diamino acid in the peptidoglycan is lysine, and alanine is present. The major menaquinones present are MK-8 (37%), MK-9 (61%), and MK-10 (2%). Cells contain phosphatidylethanolamine and diphosphatidylglycerol as major polar lipids. The cell-wall sugars are glucose, galactose, and rhamnose. Mycolic acid not present. Major cellular fatty acids are $C_{14:0}$ (1.30%), $C_{16:0}$ (2.14%), $C_{18:0}$ (2.42%), $C_{15:0}$ iso (11.47%), $C_{15:0}$ anteiso (54.92%), $C_{15:1}$ iso (1.25%), $C_{15:1}$ anteiso (6.38%), $C_{16:0}$ iso (1.79%), $C_{16:0}$ anteiso (1.76%), $C_{17:0}$ anteiso (6.48%), and $C_{19:0}$ iso (1.07%).

Source: Antarctic sea sediments near the Larsemann Hill area.

DNA G+C content (mol%): 68 ± 0.5 (T_m).

Type strain: SPC26, LMG 24542, NCCB 100228.

Sequence accession no. (16S rRNA gene): AM931709.

8. **Arthrobacter ardleyensis** Chen, Xiao, Wang, Zeng and Wang 2005b, 2235[VP] (Effective publication: Chen, Xiao, Wang, Zeng and Wang 2005a, 304.)

ard.ley.en′sis. N.L. masc. adj. *ardleyensis* of or pertaining to Ardley, where the type strain was isolated.

Individual cells show a distinct rod–coccus cycle; some cells are arranged at an angle in V formation, Gram-stain-positive, easily decolorized, rods; motile, aerobic to slightly anaerobic. Catalase is positive, oxidase is negative, and spores or capsules not seen. Colonies in Luria–Bertani medium at 25°C are yellow, circular, convex, smooth, or crumpled in old culture, entire margins, slightly glistening, and semitransparent in young culture. Growth occurs with a suitable carbon source in mineral salts medium; no additional growth factors were required. Grows at 0–30°C; optimal growth temperature is around 25°C. No growth after 30 min at 60°C. Growth is good in 0–3% NaCl and tolerates up to 10% NaCl. Growth is optimal at pH 7.0–8.5. Hydrolyzes Tween 80 and casein but not starch, cellulose, xylan, chitin, and algin. Nitrate is reduced. Methyl red test, Voges–Proskauer test, indole, and H_2S production are negative. NH_3 production is positive. Arginine dihydrolase is produced, but uricase and tryptophan deaminase are negative. Sensitive to (in μg/ml) ampicillin (100) and chloramphenicol (12.5), but resistant to (in μg/ml) kanamycin (50). A Biolog test showed that the following compounds were utilized for respiration: dextrin, glycogen, Tween 40, Tween 80, L-arabinose, D-arabitol, D-cellobiose, D-fructose, D-galactose, α-D-glucose, D-mannose, maltotriose, maltose, DL-α-glycerolphosphatase, D-ribose, L-rhamnose, D-psicose, palatinose, sucrose, D-tagatose, D-trehalose, turanose, D-xylose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenyl-acetic acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, pyruvic acid methyl ester, succinic acid mono-methyl ester, propionic acid, pyruvic acid, succinamic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-pyroglutamic acid, L-serine, putrescine, glycerol, adenosine, and 2′-deoxy adenosine. Negative reactions are observed with α-cyclodextrin, β-cyclodextrin, inulin, mannan, arbutin, amygdalin, *N*-acetyl-β-D-mannosamine, *N*-acetyl-D-glucosamine, L-fucose, D-galacturonic acid, gentiobiose, α-D-lactose, lactulose, D-mannitol, D-melezitese, D-melibiose, β-methyl-D-galactoside, 3-methyl-D-glucose, β-methyl-D-glucoside, salicin, stachyose, uridine, uridine-5′-monophosphate, and α-D-glucose 1-phosphate. The interpeptide bridges of the peptidoglycan consist of alanine and glutamic acid. The peptidoglycan type is A4α. The major menaquinones are MK-8 and MK-9. The cellular fatty acid pattern is dominated by $C_{15:0}$ anteiso.

Source: Antarctic Ardley lake sediment.

DNA G+C content (mol%): 55.2–59.5 (HPLC).

Type strain: An25, CGMCC 1.3685, JCM 12921.

Sequence accession no. (16S rRNA gene; type strain): AJ551163.

Sequence accession no. (16S rRNA gene; other strains): AJ551162, AJ715981.

9. **Arthrobacter arilaitensis** Irlinger, Bimet, Delettre, Lefèvre and Grimont 2005, 459[VP]

a.ri.lai.ten′sis. N.L. masc. adj. *arilaitensis* pertaining to Arilait, arbitrary name formed to honor Arilait-Recherches, a research association that coordinates the collective research programmes of the professional French dairy federations.

The description was based on the study of nine strains. Cells are aerobic, Gram-stain-positive, catalase-positive, oxidase-negative, non-spore-forming, nonmotile, and exhibit a rod–coccus growth cycle. Colonies on BHI agar are yellow, round, smooth, convex, and 2 mm in diameter. Grows between 10°C and 30°C and tolerates up to 10% (w/v) NaCl. Gelatinase, β-galactosidase, pyrazinamidase, pyrrolidonyl arylamidase, phosphatase, and α-glucosidase are produced. Urease and esculin are not hydrolyzed. Nitrate is not reduced. Glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen are not fermented. In Biotype 100 strips using biotype 2 medium, most strains (>89%) are able to use the following substrates as sole carbon sources: D-glucose, maltotriose, maltose, α-lactose, D-arabitol, glycerol, 5-keto-D-gluconate, D-gluconate, protocatechuate, 4-hydroxybenzoate, lactate, glycerate, and tyrosine. Other substrates are used less frequently (11–88%): D-galactose, sucrose, D-fructose, D-trehalose, D-mannose, lactulose, L-arabinose, D-ribose, D-xylose, malonate, propionate, 2-oxoglutarate, malate, putrescine, succinate, fumarate, D-glucosamine, 3-hydroxybenzoate, 3-hydroxybutyrate, aspartate, glutamate, proline, alanine, L-histidine, serine, methyl-β-galactopyranoside, D-cellobiose, β-gentiobiose, esculin, D-turanose, D-sorbitol, aconitate, citrate, D-glucuronate, 2-keto-D-gluconate, L-tryptophan, phenylacetate, 4-aminobutyrate, caprylate, and 5-aminovalerate. The following carbon sources are not utilized: sorbose, D-melibiose, D-raffinose, methyl-α-galactopyranoside, methyl-β-glucopyranoside, palatinose, L-rhamnose, fucose, D-melezitose, L-arabitol, xylitol, dulcitol, tagatose, *myo*-inositol, D-mannitol, maltitol, adonitol, lyxose, erythritol, methyl-

α-D-glucopyranoside, methyl-D-glucopyranose, saccharate, mucate, tartrate, tricarballylate, D-galacturonate, *N*-acetyl-D-glucosamine, quinate, gentisate, benzoate, 3-phenylpropionate, *m*-coumarate, trigonelline, betaine, histamine, caprate, glutarate, ethanolamine, tryptamine, and itaconate. The type strain Re117 utilizes the following substrates as sole carbon sources: D-glucose, D-galactose, D-trehalose, sucrose, maltotriose, maltose, lactose, D-cellobiose, ribose, L-arabinose, D-xylose, D-arabitol, glycerol, turanose, 5-keto-D-gluconate, D-gluconate, protocatechuate, 4-hydroxybenzoate, lactate, glycerate, aspartate, glutamate, alanine, serine, and tyrosine.

The cell wall contains lysine, alanine, and glutamic acid. The whole-cell sugars are galactose, glucose, ribose, and mannose.

Source: the surface of Reblochon cheese.

DNA G+C content (mol%): not determined.

Type strain: Re117, CIP 108037, DSM 16368, JCM 13566.

Sequence accession no. (16S rRNA gene; type strain): AJ609628.

Sequence accession no. (16S rRNA gene; other strains): AJ609621, AJ609622, AJ609623, AJ609624, AJ609625, AJ609626, AJ609627, AJ609628.

10. **Arthrobacter aurescens** (*ex* Clark 1951) Phillipps 1953, 241[AL] (*Arthrobacter globiforme* var. aurescens Clark 1951, 180)

au.res′cens. L. v. *auresco* to become golden; L. part. adj. *aurescens* becoming golden.

Colonies of the type strain are reported to show a yellow pigmentation on agar and other media but this strain gives only pale buff colonies on yeast extract-peptone agar when incubated in the dark. When supplied with biotin, growth occurs in suitable mineral salts medium with an ammonium salt or nitrate as nitrogen source and glucose as carbon and energy source (Keddie et al., 1966; Owens and Keddie, 1969). Starch is hydrolyzed, nitrate is not reduced, and there is no growth in 10% NaCl. Nicotine blue is not produced from nicotine. Utilizes L-arginine, L-asparagine, L-histidine, L-arabinose, D-galactose, D-glucose, D-ribose, D-xylose, butanediol, histidinol, 4-aminobutyrate and ρ-hydroxybenzoate but not L-leucine, L-rhamnose, inositol, or malonate. Assimilates adipic acid, citric acid, formic acid, and uric acid but not benzoic acid, glutaric acid, malonic acid, pimelic acid, or propionic acid. Urea is formed from uric acid. Nonmotile (Kodama et al., 1992). Oxidase-positive. Esculin is hydrolyzed. Elastase but not pyrrolidonyl arylamidase is produced. Gluconate is utilized. The following compounds are utilized for respiration: α-cyclodextrin, D-xylose (weak reaction), arbutin (weak reaction), D-melibiose (weak reaction), 3-methylglucose (weak reaction), and D-raffinose (weak reaction). Uridine, sucrose, propionic acid, and salicin are not used for respiration (Kotoučková et al., 2004). The cell-wall peptidoglycan is of the Lys–Ala–Thr–Ala type (A3α) (Fiedler et al., 1970). The whole-cell sugar is galactose (mannose). The major isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986). The predominant fatty acid is $C_{15:0}$ anteiso (~66%), followed by $C_{17:0}$ anteiso (~26%). (Kodama et al., 1992)

Sequence accession no. (16S rRNA gene): X83405.

Sequence accession no. (recA): AF214793.

11. **Arthrobacter bergerei** Irlinger, Bimet, Delettre, Lefèvre and Grimont 2005, 459[VP]

ber.ge′re.i. N.L. gen. masc. n. *bergerei* of Bergère, to honor Jean-Louis Bergère, a French microbiologist.

The description is based on the results of studies of five strains. Cells are aerobic, Gram-stain-positive, catalase-positive, oxidase-negative, non-spore-forming, and nonmotile. They exhibit a rod–coccus growth cycle. Colonies on BHI agar medium are yellow, round, smooth, convex and 2–3 mm in diameter. Grows between 10°C and 30°C and tolerates up to 7.5% (w/v) NaCl. Produce β-galactosidase, pyrazinamidase, pyrrolidonyl arylamidase, and α-glucosidase but not urease, phosphatase, β-glucuronidase, and gelatinase. Esculin is not hydrolyzed. Nitrate is not reduced. D-Glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen are not fermented. In Biotype 100 strips using biotype 2 medium, all strains (100%) are able to use the following substrates as sole carbon sources: D-glucose, fructose, D-galactose, sucrose, maltose, lactose, ribose, L-arabinose, D-xylose, D-glycerol, D-gluconate, quinate, protocatechuate, lactate, aspartate, and glutamate. Other substrates are used less frequently (20–80%): lactulose, D-cellobiose, L-rhamnose, D-melezitose, D-mannitol, turanose, D-trehalose, D-mannose, maltotriose, arabitol, methyl-β-galactopyranoside, aconitate, citrate, 2-keto-D-gluconate, L-tryptophan, 4-hydroxybenzoate, 3-hydroxybenzoate, phenylacetate, malate, 5-keto-D-gluconate, betaine, 5-aminovalerate, ethanolamine, malonate, 3-phenylpropionate, coumarate, 4-aminobutyrate, benzoate, putrescine, glucosamine, 3-hydroxybutyrate, histidine, L-alanine, serine, propionate, 2-oxoglutarate, proline, D-alanine, and tyrosine. The following carbon sources are not utilized: sorbose, D-melibiose, D-raffinose, methyl-α-galactopyranoside, β-gentiobiose, methyl-β-glucopyranoside, esculin, palatinose, fucose, L-arabitol, xylitol, dulcitol, tagatose, *myo*-inositol, maltitol, D-sorbitol, adonitol, lyxose, erythritol, methyl-α-D-glucopyranoside, methyl-D-glucopyranose, saccharate, mucate, D-, L-, and *meso*-tartrate, tricarballylate, D-glucuronate, D-galacturonate, *N*-acetyl-D-glucosamine, gentisate, trigonelline, histamine, caprate, caprylate, glutarate, glycerate, tryptamine, and itaconate. The type strain Ca106 utilizes the following substrates as sole carbon sources: D-glucose, fructose, D-galactose, D-mannose, sucrose, lactulose, methyl-β-galactopyranoside, maltotriose, maltose, lactose, D-cellobiose, ribose, L-arabinose, D-xylose, D-arabitol, glycerol, D-gluconate, aconitate, citrate, phenylacetate, quinate, protocatechuate, 3-hydroxybenzoate, benzoate, 4-hydroxybenzoate, putrescine, 4-aminobutyrate, lactate, histidine, glucosamine, aspartate, glutamate, 3-hydroxybutyrate, proline, D-alanine, L-alanine, serine, propionate, and tyrosine. The cell wall contains lysine, alanine, and glutamic acid. The whole-cell sugars are glucose, ribose, and mannose.

Source: the surface of Camembert cheese.

12. **Arthrobacter castelli** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1461[VP]

cas.tel′li. L. gen. n. *castelli* of the castle.

Cells are Gram-stain-positive, short rods and cocci (diameter 0.8–1 μm) occurring in pairs and chains. They are nonmotile and do not form endospores. Colonies on NA after 48 h are small (<1 mm), light yellow, round with entire margins, of low convexity, opaque, and smooth. No growth in an anaerobic chamber on NA. Optimal temperature for growth is 22–37°C. Weak growth at 15°C and no growth at 10 or 45°C. Poor growth on media without NaCl. Catalase-positive and oxidase-negative. By using the API CORYNE system, positive reactions are observed for pyrazinamidase, alkaline phosphatase, β-glucuronidase, β-galactosidase, α-glucosidase, and urease. Negative reactions are obtained for nitrate reduction, pyrrolidonyl arylamidase, *N*-acetyl-β-glucosaminidase, esculin (β-glucosidase), gelatinase, and fermentation of glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen. Using the API ZYM system, activity is detected for alkaline phosphatase, acid phosphatase (weak), esterase C4 (weak), esterase lipase C8, lipase C14 (weak), leucine arylamidase, trypsin (weak), phosphoamidase (weak), and α-glucosidase. No activity is detected for valine arylamidase, cystine arylamidase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, or α-fucosidase. Predominant fatty acids are $C_{15:0}$ anteiso (51%) and $C_{15:0}$ iso (23%). The peptidoglycan type is A3α Lys–Ala–Ser–Ala_3. MK-9(H_2) is the predominant menaquinone (75%), while MK-10(H_2) and MK-9 occur in small amounts. The cell-wall sugars are galactose, xylose, and rhamnose. Polar lipids are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and one unknown glycolipid.

Source: a rosy biofilm overgrowing a mural painting in the Saint-Catherine chapel (castle of Herberstein, Austria).

DNA G+C content (mol%): 68.1 (HPLC).

Type strain: DSM 16402, JCM 21794, LMG 22283.

Sequence accession no. (16S rRNA gene): AJ639826.

13. **Arthrobacter chlorophenolicus** Westerberg, Elväng, Stackebrandt and Jansson 2000, 2090[VP]

chlo.ro.phe.no′li.cus. N.L. n. *chlorophenol* chlorophenol; L. masc. suff. *-icus* suffix used with the sense of pertaining to; N.L. masc. adj. *chlorophenolicus* pertaining to chlorophenols.

Cells are Gram-stain-positive and display a rod–coccus life cycle. The cocci are ~0.75 μm in diameter. The rods are ~0.5–0.7 μm wide and 1–4 μm, depending on the stage in the life cycle and composition of the growth medium. Agar colonies are circular, smooth, and pearl gray in color. Spores are not formed. Growth occurs with a suitable carbon source in mineral salts medium; no additional growth factors are needed. Red to black pigment is formed from several phenolic compounds, only during incubation with shaking from phenols that can be used for growth, and both with and without shaking for phenols that cannot be used for growth. Catalase-positive. Motile. Obligately aerobic. Grows at 3–37°C and optimally between 20 and 30°C. Grows on acetate, ethanol, glycerol, creatine, uric acid, succinate, glucose, tyrosine, ascorbic acid, nicotine, and weakly on creatinine. Niacin and methanol are not utilized. Testing with Biolog showed that the following compounds are oxidized: dextrin, glycogen, D-fructose, D-galactose, D-gluconic acid, α-D-glucose, maltose, maltotriose, D-mannose, D-melezitose, D-melibiose, D-psicose, D-raffinose, D-ribose, stachyose, sucrose, turanose, acetic acid, β-hydroxybutyric acid, ρ-hydroxyphenylacetic acid, α-ketoglutaric acid, D-lactic acid methyl ester, L-malic acid, methyl pyruvate, pyruvic acid, *N*-acetyl-L-glutamic acid, D-alanine, L-alanine, L-alanylglycine, L-asparagine, L-glutamic acid, L-pyroglutamic acid, L-serine, and putrescine. The following substrates were not used for respiration: inulin, α-cyclodextrin, β-cyclodextrin, Tween 40,Tween 80, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, L-arabinose, L-arabitol, arbutin, L-fucose, D-galacturonic acid, α-D-lactose, β-methyl-D-galactoside, α-methyl-D-glucoside, β-methyl-D-glucoside, α-methyl-D-mannoside, salicin, sedoheptulosan, D-tagatose, γ-hydroxybutyric acid, α-ketovaleric acid, lactamide, 2,3-butanediol, 2-deoxyadenosine, inosine, thymidine, adenosine-5′-monophosphate, thymidine-5′-monophosphate, uridine-5′-monophosphate, fructose 6-phosphate, glucose 1-phosphate, glucose 6-phosphate, and D-L-α-glycerol phosphate. The cellular fatty acid content is as follows: $C_{15:0}$ anteiso (66%), $C_{16:0}$ iso (10%), $C_{15:0}$ iso (7%), $C_{17:0}$ anteiso (5%), $C_{14:0}$ iso (4%), $C_{16:0}$ (3%), $C_{14:0}$ (2%), $C_{16:1}$ iso h (1%), $C_{16:1}$ ω7*c* (1%), and $C_{17:1}$ anteiso ω9*c* (1%). The cell-wall diamino acid is lysine. The peptidoglycan type is A3α with an L-Lys–L-Ser–L-Thr–L-Ala interpeptide bridge.

Source: soil at Fort Collins, CO, USA.

DNA G+C content (mol%): 65.1 (T_m).

Type strain: A6, ATCC 700700, CIP 107037, DSM 12829, JCM 12360.

Sequence accession no. (16S rRNA gene): AF102267.

Sequence accession no. (complete genome): CP001341.

14. **Arthrobacter citreus** Sacks 1954, 342[AL]

ci′tre.us. L. masc. adj. *citreus* of or pertaining to the citron-tree; intended to mean lemon-yellow, lemon-colored.

The rods are feebly motile. Colonies on yeast extract-peptone media have a yellow, nondiffusible pigment which is insoluble in ether and acetone. Biotin, thiamine, nicotinic acid, tyrosine, methionine, cysteine, and a siderophore such as ferrichrome or mycobactin are required for growth. The siderophores can be replaced by certain synthetic metal chelators. The type strain used about 40 of 180 compounds tested as sole or principal sources of carbon + energy. They included a relatively wide range of carbohydrates, sugar derivatives, and amino acids, together with some fatty acids, dicarboxylic acids, hydroxyacids, oxoacids, non-nitrogenous aromatic compounds, amines, and heterocyclic compounds. Of those tested, no simple alcohols, polyalcohols, or glycols were utilized (Keddie et al.,

1986). Starch is hydrolyzed, nitrate is reduced, and growth occurs in the presence of 10% NaCl. Nicotine blue is not produced from nicotine. Utilizes L-arginine, L-asparagine, L-histidine, L-arabinose, D-galactose, D-glucose, L-rhamnose, D-ribose, D-xylose, 4-aminobutyrate, and malonate but not L-leucine, butanediol, histidinol, inositol, or ρ-hydroxybenzoate. Assimilate citric acid, formic acid, malonic acid, and propionic acid but not adipic acid, benzoic acid, glutaric acid, pimelic acid, or uric acid. Urea is formed from creatinine but not from uric acid. Motile (only the type strain was investigated; Kodama et al., 1992). The type strain is positive for gelatin-, DNase-, Tween 80-, and tyrosine decomposition, β-galactosidase, and α-glucosidase but not for citrate decomposition, pyrrolidonyl peptidase, or *N*-acetylglucosaminidase. Acid is produced from glucose and mannitol (Wauters et al., 2000a). The cell-wall peptidoglycan is of the Lys–Thr–Ala_2 type (A3α) (Fiedler et al., 1970). The only whole-cell sugar is galactose. The principal isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986). The predominant fatty acid is $C_{15:0}$ anteiso (~57%), followed by $C_{16:0}$ (~11%), $C_{17:0}$ anteiso (~8%), $C_{16:0}$ iso (~7%), and $C_{15:0}$ iso (~7%) (Kodama et al., 1992).

Source: chicken feces, but probably a dust or soil contaminant.

DNA G+C content (mol%): 62.9–63.8 (T_m).

Type strain: ATCC 11624, CCUG 23840, CIP 102363, DSM 20133, HAMBI 89, NBRC12957, JCM 1331, LMG 16338, NRRL B-1258, VKM Ac-1106.

Sequence accession no. (16S rRNA gene): X80737.

Sequence accession no. (recA): AF214781.

15. **Arthrobacter creatinolyticus** Hou, Kawamura, Sultana, Shu, Hirose, Goto and Ezaki 1998, 428[VP]

cre.a.ti.no.ly′ti.cus. N.L. n. *creatininum* creatinine; N.L. masc. adj. *lyticus* (from Gr. masc. adj. *lutikos*) able to loosen, able to dissolve; N.L. masc. adj. *creatinolyticus* creatinine-hydrolyzing.

Grows well aerobically at 37°C, and cells are nonmotile, Gram-stain-positive irregular rods with a length of about 1.4–3.6 µm and a width of 0.5–0.8 µm. Cells change into cocci in older cultures and their diameter is 0.5–0.8 µm. Colonies are circular, smooth, and yellow pigmented on brain heart infusion agar. The diameter of the colonies is about 1–1.5 mm after 24 h culture. The cell-wall amino acid components and ratio are Glu:Ala:Lys, 1.9:3.1:1. The diamino acid is lysine. MK-8 and MK-9 are the major menaquinones. Catalase is produced; creatinine, xanthine, and gelatin but not starch are hydrolyzed; and nitrate is reduced; acid is not produced from xylose, ribose, galactose, rhamnose, arabinose, xylitol, or inositol, but is produced from glycerol.

Source: human urine.

DNA G+C content (mol%): 66.0–67.0 (HPLC).

Type strain: CIP 105749, GIFU 12498, JCM 10102.

Sequence accession no. (16S rRNA gene): D88211.

16. **Arthrobacter crystallopoietes** Ensign and Ritterberg 1963, 149[AL]

crys.tal.lo.poi.e′tes. L. n. *crystallus* a crystal, Gr. v. *poieo* to make, form; N.L. masc. adj. *crystallopoietes* crystal forming.

Colonies on yeast extract-peptone media show no distinctive pigmentation. On 2-hydroxypyridine agar, a brilliant green crystalline pigment develops in the colony mass after 3 or 4 d incubation at 30°C. Nutritionally nonexacting: growth occurs in a suitable mineral salts medium with an ammonium salt or nitrate as sole nitrogen source and glucose as carbon + energy source. Starch is not hydrolyzed, nicotine is not utilized. Nonmotile (Keddie et al., 1986). Nitrate is reduced. Urease-positive. Esculin is not hydrolyzed. Inositol but not sorbitol, lactose, xylitol, xylose, glucose, maltose, mannitol, and sucrose is utilized (Li et al., 2004c). The cell-wall peptidoglycan is of the Lys–Ala type. The whole-cell sugars are galactose and glucose. The principal isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986). The predominant fatty acid is $C_{15:0}$ anteiso (75%), followed by $C_{17:0}$ anteiso (7%), $C_{16:0}$ (4%), $C_{16:0}$ iso (4%), and $C_{15:0}$ iso (3%) (Funke et al., 1996).

Source: soil by enrichment in a mineral salt medium containing 2-hydroxypyridine as sole carbon and energy and nitrogen source.

DNA G+C content (mol%): 62.9–63.8 (Bd).

Type strain: ATCC 15481, CIP 102717, DSM 20117, NBRC 14235, JCM 2522, LMG 3819, VKM Ac-1107.

Sequence accession no. (16S rRNA gene): X80738.

17. **Arthrobacter cumminsii** Funke, Hutson, Bernard, Pfyffer, Wauters and Collins 1996, 242[VP] emend. Funke, Pagano-Niederer, Sjödén and Falsen 1998, 1542 (Effective publication: Funke, Hutson, Bernard, Pfyffer, Wauters and Collins, 1996, 2362.)

cum.min′si.i. N.L. gen. masc. n. *cumminsii* of Cummins, to honor Cecil S. Cummins, a prominent American microbiologist and a pioneer of chemotaxonomy.

The cells are coryneform bacteria without irregular branching. No spores are formed. The cells are nonmotile. The organism is obligately aerobic. Colonies are whitish-grayish, smooth, slightly convex, and either of creamy or of sticky consistency and are of less than 2 mm in diameter after 24 h of incubation at 37°C in 5% CO_2 on SBA. Catalase activity is detected, but nitrate reductase activity is not. Urease activity is variable. Esculinase activity is not detected. DNase and gelatinase activities are observed within 10 d. Acid is produced from ribose but not from maltose, sucrose, mannitol, xylose, lactose, or glycogen. Acid production from glucose is variable. The CAMP reaction is negative. The following other enzyme activities are detected: esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, and phosphoamidase. The activities of pyrazinamidase, pyrrolidonyl arylamidase, alkaline phosphatase, and cystine arylamidase are variable. Chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase are not present. The peptidoglycan type is L-lysine–L-serine–L-glutamic acid. The predominant fatty acid is $C_{15:0}$ anteiso. Significant amounts of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{16:0}$, and $C_{17:0}$ anteiso are present, depending on the strain. The type strain possesses an A4α, L-lysine–L-serine–L-glutamic acid type murein, but the α-carboxyl group of the D-glutamic acid of the peptide subunit is substituted by a Gly residue.

Sequence accession no. (16S rRNA gene): X93354.

18. **Arthrobacter defluvii** Kim, Lee, Oh, Kim, Eom and Lee 2008, 1919[VP]

de.flu'vi.i. L. gen. n. *defluvii* of sewage.

Cells are aerobic, Gram-stain-positive, nonmotile, nonsporeforming, and display a rod–coccus life cycle. The cocci are approximately 0.6 µm in diameter. The rods are approximately 0.4–0.66 × 1.0–2.0 µm in size. Catalase-positive but oxidase-negative. Growth occurs at 5–37°C (optimum 25–30°C) and at pH 6–10 (optimum pH 7–8). Growth occurs in the presence of up to 5% NaCl but not with 10% NaCl. Colonies are creamy white, translucent, and circular with entire edges. Indole and H_2S are not produced. Voges–Proskauer reaction is positive. Nitrate is reduced but nitrite is not. Esculin, casein, and starch (weakly) are hydrolyzed, but gelatin and urea are not. Acid is produced from ribose, D-xylose, inositol, mannitol, and esculin, but not from glycerol, erythritol, D-arabinose, L-arabinose, L-xylose, adonitol, methyl-β-D-xylose, galactose, glucose, fructose, mannose, sorbose, rhamnose, dulcitol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, inulin, melezitose, raffinose, starch, glycogen, xylitol, gentiobiose, turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-ketogluconate, or 5-ketogluconate. The following compounds are utilized as sole carbon sources: mannitol, rhamnose, D-glucose, salicin, D-ribose, melibiose, L-fucose, sucrose, maltose, mannose, L-arabinose, propionate, malonate, valerate, acetate, citrate, gluconate, DL-lactate, malate, phenylacetate, histidine, L-alanine, 2-ketogluconate, 5-ketogluconate, 3-hydroxybutyrate, glycogen, 3-hydroxybenzoate, 4-hydroxybenzoate, L-proline, and L-serine. The following carbon sources are not utilized: *N*-acetylglucosamine, inositol, D-sorbitol, adipate, itaconate, suberate, and caprate. According to the results from the API ZYM tests, 2-naphthyl butyrate, L-leucyl 2-naphthylamide, 2-naphthyl phosphate (pH 5.4), 6-bromo-2-naphthyl-α-D-galactopyranoside, and 2-naphthyl-α-D-glucopyranoside are hydrolyzed, but 2-naphthyl phosphate (pH 8.5), 2-naphthyl caprylate, 2-naphthyl myristate, L-valyl-2-naphthylamide, L-cystyl-2-naphthylamide, *N*-benzoyl-DL-arginine-2-naphthylamide, *N*-glutaryl-phenylalanine 2-naphthylamide, naphthol-AS-BI-phosphate, 2-naphthyl-β-D-galactopyranoside, naphthol-AS-BI-β-D-glucuronide, 6-bromo-2-naphthyl-β-D-glucopyranoside, 1-naphthyl-*N*-acetyl-β-D-glucosaminide, 6-bromo-2-naphthyl-β-D-mannopyranoside, and 2-naphthyl-α-L-fucopyranoside are not hydrolyzed. The major menaquinone is MK-9(H_2); small amounts of MK-8(H_2) and MK-7(H_2) are also present. Predominant fatty acids are $C_{15:0}$ anteiso (56.4 ±0.4 %), $C_{16:0}$ iso (13.7±0.8 %), and $C_{15:0}$ iso (12.3±2.1 %). Cell-wall peptidoglycan is of A3α type with an L-Lys–L-Ser–L-Thr–L-Ala interpeptide bridge. Cell-wall sugars are galactose, glucose, and rhamnose.

Sequence accession no. (16S rRNA gene; another strain): AM409362.

19. **Arthrobacter echigonensis** Ding, Hirose and Yokota 2009, 859[VP]

echi.go.nen'sis. N.L. masc. adj. *echigonensis* of or pertaining to the Echigo region, in Japan.

Cells are nonmotile and non-spore-forming. Gram-stain positive, catalase-positive, oxidase-negative. Cells show a rod–coccus growth cycle and produce non-fluorescent pigment. Growth occurs on nutrient broth agar at 10–40°C, optimal temperature for growth is 30°C. Grows in presence of 3–5% NaCl (w/v) but not in the presence of 7% NaCl. The pH range for growth is 6–10 and the optimum pH is 7. Colonies are round, convex, glossy, with entire margins and are light gray or light yellow. Using the API CORYNE system, positive reactions are observed for activities of pyrazinamidase, pyrrolidonyl arylamidase, and for the utilization of glucose, ribose, and sucrose. Negative reactions are obtained for nitrate reduction, hydrolysis of gelatin, urease activity, and for the utilization of xylose, mannitol, lactose, and glycogen. Utilization of maltose is weak. Using the API ZYM system, activity is detected for alkaline phosphatase, acid phosphatase, esterase C4, esterase lipase C8, leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase β-galactosidase, β-glucuronidase, α-glucosidase, and α-mannosidase. No activity detected for lipase C14, α-chymotrypsin, α-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{15:0}$ iso. The diamino acid of the cell-wall peptidoglycan is lysine and the major components are lysine, serine, and alanine. The menaquinone content is MK-9(H_2) (83%), MK-10(H_2) (6%), and MK-8(H_2) (4%).

Sequence accession no. (16S rRNA gene): AB248531.

20. **Arthrobacter flavus** Reddy, Aggarwal, Matsumoto and Shivaji 2000, 1559[VP]

fla'vus. L. masc. adj. *flavus* yellow, the color of a pigment that the bacterium produces.

Cells are aerobic, Gram-stain-positive, non-spore-forming, nonmotile, and non-fermentative; they exhibit a rod–coccus growth cycle. Colonies on peptone-yeast extract medium are yellow, round, smooth, convex, and 0.5–2 mm in diameter. The pigment is insoluble in water but soluble in methanol and has a complex absorption spectrum with maxima at 410, 440, and 470 nm. Pigment production is not dependent on growth conditions or media composition. No growth factors

are required. Grows between 5 and 30°C, at pH 6–9, and tolerates up to 11.5% (w/v) NaCl. Optimal growth is observed at 25°C and pH 7. Positive for catalase, lipase, gelatinase, and β-galactosidase but negative for oxidase, urease, phosphatase, indole production, nitrate reduction, and levan formation. Unable to utilize a number of carbon compounds, such as sucrose, rhamnose, cellulose, arabinose, mellibiose, cellobiose, galactose, sucrose, fructose, mannose, trehalose, xylose, mannitol, raffinose, glycerol, ribose, lactose, lactic acid, adonitol, maltose, glucose, glucosamine, sorbitol, melezitol, β-hydroxybutyric acid, dulcitol, glucose, polyethylene glycol, glycine, lysine, sodium citrate, sodium acetate, sodium succinate, cellulose, inulin, *meso*-inositol, glutamic acid, L-alanine, phenylalanine, methionine, glutamine, arginine, serine, potassium hydrogen phosphate, myristic acid, ammonium formate, creatine, methanol, tyrosine, sodium pyruvate, glycogen, erythritol, tryptophan, ethanol, and sodium thioglycolate. Able to utilize sorbitol as the only source of carbon. Unable to oxidize or ferment glucose, galactose, sucrose, thioglycolate, or mannose but able to acidify sucrose and hydrolyze esculin but not starch or cellulose. Sensitive to all antibiotics (in μg) tested: carbenicillin (50), tobramycin (15), chlortetracycline (30), polymyxin B (300), oxytetracycline (30), rifampin (5), nitrofurantoin (300), penicillin (10), bacitracin (10), nitrofurazone (10), gentamicin (10), lincomycin (2), furazolidone (50), colistin (10), furoxone (100), kanamycin (30), nystatin (100), cotrimoxazole (25), chloramphenicol (30), ampicillin (10), tetracycline (30), amoxicillin (100), trimethoprim (5), and erythromycin (15). The cell-wall peptidoglycan type is Lys–Thr–Ala_3 (the A3α variant), and the major menaquinone is MK-9(H_2). The cell-wall sugars are galactose, glucose, and ribose.The cellular fatty acids are $C_{14:0}$, $C_{15:0}$, $C_{15:0}$ anteiso, $C_{16:0}$, $C_{16:0}$ iso, $C_{16:1}$, $C_{17:0}$, $C_{17:0}$ anteiso, $C_{18:0}$ iso, $C_{18:0}$, and $C_{20:0}$. The polar lipids are phosphatidylglycerol, cardiolipin, and phosphatidylethanolamine.

Source: a cyanobacterial mat sample from McMurdo Dry Valley, Antarctica.

DNA G+C content (mol%): 64.0 ±2.0 (T_m).

Type strain: CMS 19Y, JCM 11496, MTCC 3476.

Sequence accession no. (16S rRNA gene): AB299278, AB537168.

21. **Arthrobacter gandavensis** Storms, Devriese, Coopman, Schumann, Vyncke and Gillis 2003, 1882[VP]

gan.da.ven′sis. N.L. masc. adj. *gandavensis* of or belonging to *Gandavum*, the Latin name for Ghent, referring to the place where these strains were first isolated.

Cells are Gram-stain-positive, relatively small coccobacilli with one pointed end. They are catalase-positive. Bright yellow pigment is produced. Growth at 25 and 37°C is about equal; growth is less abundant at 42°C. Obligately aerobic. Cells precipitate partially in BHI broth; unable to grow in 6.5% NaCl. Acid is produced weakly from esculin, D-fructose, and ribose. No acid is produced from adonitol, amygdalin, D- or L-arabinose, D- or L-arabitol, arbutin, cellobiose, dulcitol, erythritol, D- or L-fucose, galactose, β-gentiobiose, gluconate, glycogen, glycerol, inositol, inulin, 2- or 5-ketogluconate, lactose, D-lyxose, maltose, maltotriose, mannitol, melezitose, melibiose, methyl-β-glycoside, methyl-α-D-mannoside, methyl-α-D-glucoside, D-raffinose, sucrose, salicin, sorbitol, L-sorbose, starch, D-tagatose, trehalose, D-turanose, xylitol, or D- or L-xylose. Variable in tests with D-glucose, mannose, and rhamnose. Strains are negative for pyrrolidonyl arylamidase [hydrolysis of L-pyroglutamic acid-7-amino-4-methylcoumarin (AMC)], β-glucuronidase, *N*-acetyl-β-glucosaminidase, enzymic hydrolysis of L-valine-AMC, 4MU-α-D-glucoside, 4-methylumbelliferyl (4MU)-β-D-glucuronide, L-isoleucine-AMC, *p*-nitrophenyl-β-D-cellobioside, and *p*-nitrophenyl-α-D-maltoside. Variable in tests for L-arginine-AMC, L-pyroglutamic acid-AMC, L-tryptophan-AMC, 4MU-*N*-acetyl-β-D-glucosaminide, 4MU-phosphate, 4MU- β-D-glucuronide, and gelatin liquefaction. Cell-wall peptidoglycan is based on the A3α type (L-Lys–L-Thr–L-Ala–L-Ala); major menaquinone is MK-9(H_2). Predominant cellular fatty acid is $C_{15:0}$ anteiso; significant amounts of $C_{15:0}$ iso and $C_{17:0}$ anteiso are also present.

Source: mammary and uterine infections in cattle; its pathogenic role in these processes is uncertain.

DNA G+C content (mol%): 65.0 (HPLC).

Type strain: DSM 15046, JCM 13316, LMG 21285.

Other strains: LMG 21286, LMG 21887.

Sequence accession no. (16S rRNA gene; type strain): AJ316140.

Sequence accession no. (16S rRNA; other strains): AJ491107, AJ491108.

22. **Arthrobacter gangotriensis** Gupta, Reddy, Delille and Shivaji 2004, 2376[VP]

gan.go.tri.en′sis. N.L. masc. adj. *gangotriensis* of or pertaining to the Indian Antarctic station Dakshin Gangotri.

Cells are aerobic, psychrotolerant, Gram-stain-positive, nonmotile, non-spore-forming, and yellow-pigmented: they exhibit a rod–coccus cycle. Grows between 4 and 30°C. The optimum temperature and pH for growth are 22°C and pH 7. Growth occurs in the presence of 6% NaCl. Positive for catalase, oxidase, phosphatase, urease, and gelatinase and negative for methyl red, indole, and Voges–Proskauer tests, β-galactosidase, arginine dihydrolase, lysine decarboxylase, and arginine decarboxylase. Does not hydrolyze esculin, Tween 80, or starch and does not reduce nitrate to nitrite. Acid is produced from D-fructose, D-galactose, and D-mannose but not from D-arabinose, D-glucose, lactose, D-mannitol, D-rhamnose, D-ribose, sucrose, or D-xylose. Can utilize adonitol, D-arabinose, D-cellobiose, dulcitol, D-galactose, inulin, D-fructose, D-glucose, pyruvate, lactose, D-maltose, D-mannose, D-melibiose, D-ribose, sorbitol, sucrose, D-xylose, xylitol, L-arginine, L-asparagine, L-glycine, and L-phenylalanine but not glycerol, D-mannitol, D-rhamnose, trehalose, L-alanine, L-glutamic acid, L-histidine, L-leucine, or tryptophan as sole carbon sources. Resistant to nalidixic acid and nitrofurantoin but sensitive to amikacin, ampicillin, cefoperazone, cefuroxime, ciprofloxacin, co-trimoxazole, erythromycin, chloramphenicol, kanamycin, lincomycin, lomefloxacin, norfloxacin, penicillin, roxithromycin, streptomycin, tetracycline, tobramycin, and vancomycin. The major menaquinones MK-8, MK-9, and MK-10 are present in the ratio 1:4.5:2. The cellular fatty acids at 25°C are $C_{15:0}$ anteiso (61.6%), $C_{17:0}$ anteiso (5.8%), $C_{18:1}$ (9.0%), $C_{17:0}$ iso (5.5%), $C_{16:0}$ iso (4.0%), $C_{15:0}$ iso (3.0%), and $C_{16:1}$ (4.2%).

The yellow pigment is insoluble in water but soluble in methanol and exhibits three absorption maxima, at 494, 528, and 571.5 nm. The cell-wall peptidoglycan type is Lys–Glu (variation A4α).

Source: penguin rookery soil.

DNA G+C content (mol%): 66.0 (method of analysis specified in Shivaji et al., 1989).

Type strain: DSM 15796; JCM 12166.

Sequence accession no. (16S rRNA gene): AJ606061.

23. **Arthrobacter histidinolovorans** Adams 1954, 832[AL]

his.ti.di.no.lo.vo′rans. N.L. n. *histidinolum* histidinol; L. part. adj. *vorans* devouring, consuming; N.L. part. adj. *histidinolovorans* histidinol destroying.

Nonmotile. Colonies on yeast extract-peptone media show no distinctive pigmentation. When supplied with biotin, growth occurs in a suitable mineral salts medium with an ammonium salt as sole nitrogen source and glucose as sole carbon and energy source. Utilizes L-histidinol as major source of carbon and energy and nitrogen when grown in mineral salts medium containing a low concentration of yeast extract (Keddie et al., 1986). There is no hydrolysis of starch, no reduction of nitrate, and no growth in 10% NaCl. Nicotine blue is not produced from nicotine. Utilizes L-arginine, L-asparagine, L-histidine, L-arabinose, D-galactose, D-glucose, L-rhamnose, D-ribose, D-xylose, L-histidinol, inositol, 4-aminobutyrate, and ρ-hydroxybenzoate but not L-leucine, butanediol, or malonate. Assimilates citric acid, formic acid, glutaric acid, propionic acid, and uric acid but not adipic acid, benzoic acid, malonic acid, and pimelic acid. Urea is formed from creatinine and uric acid (Kodama et al., 1992). The cell-wall peptidoglycan is of the Lys–Ala–Thr–Ala type (A3α). The whole-cell sugars are galactose and glucose. The principal isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986). The predominant fatty acid is $C_{15:0}$ anteiso (~64%), followed by $C_{17:0}$ anteiso (~26%) (Kodama et al., 1992).

Source: soil on mineral agar medium containing L-histidinol as carbon and energy and nitrogen source.

DNA G+C content (mol%): 61.3 (Bd).

Type strain: ATCC 11442, CCUG 23888, CIP 106988, DSM 20115, NBRC 15510, JCM 2520, LMG 3822, VKM Ac-1978.

Sequence accession no. (16S rRNA gene): X83406.

Sequence accession no. (recA): AF214788.

24. **Arthrobacter humicola** Kageyama, Morisaki, Ōmura and Takahashi 2008, 56[VP]

hu.mi′co.la. L. masc. n. *humus* soil; L. suff. *-cola* dweller; N.L. masc. or fem. n. *humicola* soil dweller.

Cells have a rod–coccus cycle. Gram-stain-positive, motile by flagella, and aerobic. Colonies are cream colored on YD agar. Growth occurs on YD agar at initial pH 6–10 and at 4–34°C. In YD agar medium, up to 3% NaCl is tolerated. D-Glucose, D-xylose, raffinose, melibiose, D-mannitol, L-rhamnose, L-inositol, and sucrose are assimilated, but L-arabinose and cellulose are not. Esterase (C4), leucine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, and α-glucosidase are detected by the API ZYM enzyme assay; the assay is negative for alkaline phosphatase, trypsin, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase. Weak reactions are detected for esterase lipase (C8), lipase (C14), valine arylamidase, β-galactosidase, β-glucosidase, and α-mannosidase. Catalase is detected by the API Coryne enzyme assay, but nitrate reductase, pyrrolidonyl arylamidase, and urease are negative. The diagnostic diamino acid of the peptidoglycan is lysine. The acyl type of the peptidoglycan is acetyl. The major menaquinone is MK-9(H_2). The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. Cell-wall sugars contain galactose and rhamnose.

Source: paddy soil, Japan.

DNA G+C content (mol%): 67.0 (HPLC).

Type strain: KV-653; JCM 15921, NBRC 102056, NRRL B-24479.

Sequence accession no. (16S rRNA gene): AB279890.

25. **Arthrobacter ilicis** Collins, Jones and Kroppenstedt 1981, 384[VP] (Effective publication: Collins, Jones and Kroppenstedt 1981, 321.)

i′li.cis. N.L. n. *Ilex -icis*, a scientific botanical genus name; N.L. gen. n. *ilicis*, of *Ilex*.

Surface colonies on nutrient agar are 0.75–1 mm diameter after 1–2 d, becoming larger (2–4 mm) on extended incubation; convex with entire margin, shiny; yellow pigment produced. Cells show a marked change of form during the growth cycle in complete media. Older cultures are composed entirely of largely of coccoid cells which, on transfer to suitable fresh medium, give rise to irregular rods characteristic of exponential phase cultures. Many cells are arranged at an angle to each other to give V-formations. As growth proceeds, the rods become shorter and are eventually replaced by the coccoid cells characteristic of stationary phase cultures (Cure and Keddie, 1973). Does not required B-vitamins: growth occurs in a mineral salts medium containing an ammonium salt and with glucose as carbon and energy source only when Casamino acids are supplied. Gram-stain-positive, non-acid-fast; endospores are not formed. Motile. Optimum growth temperature 25–30°C; growth at 4 and 10°C but not at 37°C. Slight growth in 5% NaCl and no growth in 10% NaCl. Aerobic, catalase- and cytochrome oxidase-positive. No growth anaerobically. Acids are not formed from glucose and other sugars in soli extract media (Jones, 1975). Weak acid production from glycerol after 5 d (Jones, 1975). Methyl red negative. Casein, chitin, gelatin, hippurate, tyrosine, Tween 20, and xanthine hydrolyzed. Urease, phosphatase, and DNase-positive. Esculin, cellulose, starch, nicotine, Tween 60, and Tween 80 are not hydrolyzed. Indole-negative. Sulfatase-negative. Nitrate is not reduced. Sensitive to erythromycin, tetracycline, and streptomycin. Utilizes L-arginine, L-asparagine, L-histidine, L-arabinose, D-galactose, D-glucose, L-rhamnose, D-ribose, D-xylose, histidinol, inositol, 4-aminobutyrate, and ρ-hydroxybenzoate but not L-leucine, butanediol, or malonate. Assimilate citric acid, formic acid, propionic acid, and uric acid but not adipic acid, benzoic acid, glutaric acid, malonic acid, and pimelic acid. Urea is formed from uric acid but not from creatinine (only type strain investigated, Kodama et al., 1992). Elastase and pyrrolidonyl arylamidase are not produced. Does not utilize

gluconate. Uses uridine, sucrose, D-melibiose (weak reaction), 3-methylglucose (weak reaction), D-raffinose (weak reaction), and salicin (weak reaction) for respiration but not arbutin and α-cyclodextrin (Kotoučková et al., 2004). The cell-wall peptidoglycan is of the Lys–Ala–Thr–Ala type (A3α). The whole-cell sugars are galactose, rhamnose, and mannose. Mycolic acids are not present. The principal isoprenoid quinone is MK-9(H_2). The fatty acid composition is mainly straight-chain, anteiso-, and iso-methyl-branched acids. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. The polar lipids comprise diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and two glycolipids.

DNA G+C content (mol%): 61.5 (T_m).

Type strain: ATCC 14264, DSM 20138, NCPPB 1228.

Sequence accession no. (16S rRNA gene): X83407.

Additional remarks: Collins et al. (1981) proposed the transfer of *Corynebacterium ilicis* (Mandel et al., 1961) to the genus *Arthrobacter* as *Arthrobacter ilicis.* Several studies however provided evidence that strain ICMP 2608 (= ICPB CI144) and DSM 20138 (= ATCC 14264 = NCPPB 1228) considered to represent the type strain of *Corynbacterium ilicis/Arthrobacter ilicis* are members of different taxa. Based on evidence from a number of publications, it is clear that DSM 20138 = ATCC 14264 = NCPPB 1228 does not show one of the original diagnostic features of *Corynebacterium ilicis,* namely pathogenicity on American holly. In contrast, pathogenicity on American holly is exhibited by ICMP 2608 = ICPB CI14 and hence corresponds with the original description of *Cornyebacterium ilicis.*

After a Request for an Opinion (Young et al., 2004), the Judicial Commission dealt with this problem at its meetings in 2005 at the IUMS Bacteriology and Applied Microbiology Congress in San Francisco. Based on several lines of evidence, the Judicial Commission ruled that the name *Arthrobacter ilicis* (Collins et al., 1982b) is exemplified by DSM 20138 = ATCC 14264 = NCPPB 1228 and that it is not a plant pathogen according to published evidence. The type strain of *Corynebacterium ilicis* (Mandel et al., 1961) is represented by the type strain ICMP 2608 = ICPB CI144 and is reported to be a pathogen of American holly. This strain has also been shown to be a member of the species *Curtobacterium flaccumfaciens,* where it is recognized as the pathotype of *Curtobacterium flaccumfaciens* pv. *ilicis* (Tindall, 2008).

26. **Arthrobacter kerguelensis** Gupta, Reddy, Delille and Shivaji 2004, 2376[VP]

ker.guel.en′sis. N.L. masc. adj. *kerguelensis* of or pertaining to Kerguelen Islands, Antarctica.

Cells are aerobic, psychrotolerant, Gram-stain-positive, nonmotile, non-spore-forming, and undergo a rod–coccus cycle. Colonies are yellow-pigmented. Grows between 4 and 30°C. The optimum temperature and pH for growth are 22°C and pH 7. Growth occurs in the presence of 6% NaCl. Positive for catalase, oxidase, phosphatase, urease, gelatinase, and lysine decarboxylase but negative for methyl red, indole and Voges–Proskauer tests, β-galactosidase, arginine dihydrolase, and arginine decarboxylase. Hydrolyzes esculin but not Tween 80 or starch, and does not reduce nitrate to nitrite. Acid is produced from D-fructose and D-xylose but not from D-arabinose, D-galactose, D-glucose, lactose, D-mannitol, D-mannose, D-rhamnose, D-ribose, or sucrose. Can utilize adonitol, D-arabinose, dulcitol, D-galactose, inulin, D-fructose, D-glucose, L-glutamic acid, L-histidine, pyruvate, lactose, D-maltose, D-mannose, D-melibiose, D-ribose, sorbitol, sucrose, D-xylose, xylitol, L-arginine, L-asparagine, L-glycine, and L-phenylalanine, D-rhamnose, trehalose but not D-cellobiose, glycerol, D-mannitol, L-alanine, L-leucine, or tryptophan as sole carbon sources. Resistant to nalidixic acid, nitrofurantoin, and norfloxacin but sensitive to amikacin, ampicillin, cefoperazone, cefuroxime, ciprofloxacin, co-trimoxazole, erythromycin, chloramphenicol, kanamycin, lincomycin, lomefloxacin, penicillin, roxithromycin, streptomycin, tetracycline, tobramycin, and vancomycin. The major menaquinones MK-8, MK-9, and MK-10 are present in the ratio 4:6:1. The major cellular fatty acids at 25°C are $C_{15:0}$ anteiso (50.0%), $C_{17:0}$ anteiso (25.4%), $C_{15:0}$ iso (6.7%), $C_{17:0}$ iso (5.1%), $C_{16:0}$ iso (4.6%), and $C_{16:1}$ (3.6%).

Source: sea water.

DNA G+C content (mol%): 58.0 (method of analysis specified in Shivaji et al., 1989).

Type strain: KGN15, DSM 15797, JCM 12165.

Sequence accession no. (16S rRNA gene): AJ606062.

27. **Arthrobacter koreensis** Lee, Lee, Pyun and Bae 2003, 1280[VP]

ko.re.en′sis. N.L. masc. adj. *koreensis* of or pertaining to Korea, where the organisms were isolated.

Gram-stain-positive and coryneform. Cells are motile. Colonies on trypticase/soy agar are round, smooth, and yellow. Tests for the reduction of nitrate, the production of catalase, indole, acetoin, pyrazinamidase, alkaline phosphatase, and α-glucosidase, and the assimilation of glucose, mannose, mannitol, maltose, gluconate, and malate are all positive. Oxidizes Tween 40, Tween 80, D-arabitol, D-ribose, xylitol, acetic acid, *p*-hydroxyphenylacetic acid, methyl pyruvate, pyruvic acid, adenosine, 2′-deoxyadenosine, inosine, thymidine, uridine, and thymidine 5′-monophosphate. Cells are alkalitolerant and do not grow at pH 6.0, but they do grow at pH 7.0–12.0, with an optimum at pH 7.0–8.0. Major isoprenoid quinones are menaquinones MK-8(H_2) and MK-9(H_2). Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. Cell-wall peptidoglycan contains Lys–Thr–Ala_2, and the whole-cell sugar is rhamnose.

Source: soil from Daejeon City in Korea.

DNA G+C content (mol%): 63.0 ±2.0 (HPLC).

Type strain: CA15-8, NBRC 16787, JCM 12361, KCTC 9922.

Sequence accession no. (16S rRNA; type strain): AY116496.

Sequence accession no. (16S rRNA; another strain): AY116497.

28. **Arthrobacter luteolus** Wauters, Charlier, Janssens and Delmée 2000b, 1699[VP] (Effective publication: Wauters, Charlier, Janssens and Delmée 2000a, 2414.)

lu.te′o.lus. L. masc. adj. *luteolus* yellowish, because of the yellow-pigmented colonies.

Cells of *Arthrobacter luteolus* are Gram-stain-positive coryneform bacteria. No spores are formed. They are motile by peritrichous flagella. Growth is obligately aerobic. Colonies are slightly yellow, smooth, and ~1.5 mm

in diameter after 24 h of incubation at 37°C on blood agar. Catalase is positive. Nitrate is reduced. No urease is detected. Gelatin and tyrosine are hydrolyzed, but not esculin. Simmons' citrate agar is alkalinized. Not susceptible to desferrioxamine. Tween esterase is negative, but DNase is positive. Pyrrolidonyl peptidase is not detected. Acid is produced oxidatively from glucose, maltose, sucrose, and xylose, but not from mannitol and lactose. Glycerol, ribose, D-xylose, D-glucose, D-fructose, D-mannitol, rhamnose, cellobiose, maltose, sucrose, trehalose, xylitol, L-fucose, and 5-keto-gluconate are utilized. Erythritol, D-arabinose, L-arabinose, L-xylose, adonitol, β-methylxyloside, galactose, L-sorbose, dulcitol, inositol, mannitol, sorbitol, α-methyl-D-mannoside, α-methyl-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, salicin, lactose, melibiose, inulin, melezitose, D-raffinose, starch, glycogen, geniobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, D-arabitol, L-arabitol, and 2-keto-gluconate are not utilized. The following enzymic activities are detected on API ZYM strips: alkaline and acid phosphatase, esterase, esterase-lipase, leucine arylamidase, trypsin, phosphoamidase, and α-glucosidase. Not present are lipase, valine arylamidase, cystine arylamidase, chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetylglucosaminidase, α-mannosidase, and α-fucosidase. The major cellular fatty acid is $C_{15:0}$ anteiso, and the peptidoglycan type is A3α L-Lys–L-Thr–L-Ala_2.

Source: an infected surgical wound.

Type strain: CF25; ATCC BAA-272, CCUG 43811, CIP 106789, DSM 13067, JCM 11676.

Sequence accession no. (16S rRNA gene): AJ243422.

29. **Arthrobacter methylotrophus** Borodina, Kelly, Schumann, Rainey, Ward-Rainey and Wood 2002a, 685[VP] (Borodina, Kelly, Schumann, Rainey, Ward-Rainey and Wood 2002b, 180)

me.thy.lo.tro′phus. N.L. n. *methylum* (from French *méthyle*, back-formation from French *méthylène*, coined from Gr. n. *methu* wine and Gr. n. *hulê* wood) the methyl radical; N.L. pref. *methylo-* pertaining to the methyl radical; Gr. n. *trophos* feeder, rearer, one who feeds; N.L. masc. adj. *methylotrophus* feeding on methyl groups.

Cells are spherical or rod-shaped, showing a rod–coccus growth cycle, 0.6 μm in diameter and 1.3 μm in length. Gram-stain-positive, forming clumps and chains in liquid culture, and are nonmotile; spores or capsules not seen; catalase-and oxidase-positive. Grows heterotrophically and aerobically on glucose, fructose, sucrose, galactose, acetate, ethanol, pyruvate, malate, succinate, citrate, serine, alanine, taurine, and yeast extract, and on alkanesulfonates (propane-, butane-, pentane-, and hexane-sulfonate) and diethylsulfone. Grows aerobically on methylated sulfur compounds (dimethylsulfone, dimethylsulfoxide, dimethylsulfide), methanol, methylamine, trimethylamine, and formaldehyde. Methylotrophic growth with dimethylsulfone uses the ribulose monophosphate cycle for formaldehyde assimilation. Methylotrophic growth with methanol uses the serine pathway for C1-assimilation. Does not grow with methanesulfonate or autotrophically on inorganic sulfur compounds. Nitrate is not reduced. Growth on dimethylsulfone occurs optimally at pH 7.2–7.5 and at 25°C. Temperature range for growth is 4–30°C with no growth at 37 or 44°C. Ammonium chloride, nitrate, methylamine, and EDTA are used as nitrogen sources for growth. Growth occurs in the presence of 1.5% (w/v) NaCl, weakly with 2.5% (w/v) NaCl, but not with 5% (w/v) NaCl. On dimethylsulfone-agar medium, they produce creamy-yellow, circular-convex colonies, 1.0–1.3 mm in diameter. MK-9(H_2) is the principal isoprenoid quinone with smaller amounts of MK-10(H_2), MK-8(H_2), MK-9, MK-7(H_2), and MK-11(H_2). The principal cellular fatty acid is $C_{15:0}$ anteiso, with $C_{15:0}$ iso, $C_{16:0}$ iso and $C_{17:0}$ anteiso also present. Peptidoglycan contains lysine as the diagnostic diamino acid, as well as alanine and glutamic acid; provisional peptidoglycan type (L-Lys–L-$Ala_{2–4}$) is an A11.5, A11.6, or A11.7 structure.

Source: soil from the root system of Tagetes minuta.

DNA G+C content (mol%): 61.0 (T_m).

Type strain: TGA, ATCC BAA-111, DSM 14008, JCM 13519.

Sequence accession no. (16S rRNA gene): AF235090.

30. **Arthrobacter monumenti** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1461[VP]

mo.nu.men′ti. L. gen. n. *monumenti* of the monument.

Cells are Gram-stain-positive, short rods and cocci (diameter 0.8–1 μm) occurring in pairs or clusters. They are nonmotile and do not form endospores. Colonies on NA after 48 h are small (<1 mm), light yellow, round with entire margins, of low convexity, opaque and smooth. No growth in an anaerobic chamber on NA. Optimal temperature for growth is 22–30°C. Weak growth at 4°C and 37°C, and no growth at 45°C. Growth on medium with 15% NaCl. Optimum pH for growth is 7–8. Catalase-positive and oxidase-negative. Using the API CORYNE system, positive reactions are observed for nitrate reduction, pyrazinamidase, β-glucuronidase, β-galactosidase, α-glucosidase, esculin (β-glucosidase), and gelatinase. Negative reactions are obtained for *N*-acetyl-β-glucosaminidase and fermentation of ribose, xylose, mannitol, and glycogen. Variable reactions are obtained for pyrrolidonyl arylamidase, urease, and fermentation of glucose, lactose, maltose, and sucrose. In the variable characters listed above for the API CORYNE tests, the type strain is positive for pyrrolidonyl arylamidase but negative for urease and fermentation of glucose, lactose, maltose, and sucrose. In API ZYM, the type strain is positive for β-galactosidase and α-glucosidase (weak) but negative for α-mannosidase. Using the API ZYM system, activity is detected for alkaline phosphatase, esterase C4, esterase lipase C8, leucine arylamidase, trypsin, acid phosphatase (weak), and phosphoamidase (weak). No activity is detected for lipase C14, valine arylamidase, cystine arylamidase, chymotrypsin, α-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. Variable reactions are obtained for β-galactosidase, α-glucosidase, and α-mannosidase. Predominant fatty acids are $C_{15:0}$ anteiso (57%) and $C_{15:0}$ iso (25%). The peptidoglycan type is A3α Lys–Ala_4. MK-9(H_2) is the predominant menaquinone (87%), while MK-7(H_2), MK-8(H_2), and MK-10(H_2) occur in only small amounts. The cell-wall sugars are galactose, xylose, and rhamnose. Polar lipids of the type strain are

phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and one unknown glycolipid.

Source: a biofilm overgrowing a mural painting in the Servilia tomb (Roman necropolis of Carmona, Spain).

DNA G+C content (mol%): 62.2 (HPLC).

Type strain: DSM 16405, JCM 21770, LMG 19502.

Sequence accession no. (16S rRNA gene): AJ315070.

31. **Arthrobacter mysorens** Nand and Rao 1972, 324[AL]

my.so'rens. N.L. masc. adj. *mysorens* of or pertaining to Mysore, India, where the organisms were isolated.

Morphology generally is as for generic description; motility doubtful, flagella not demonstrated. No data available for the peptidoglycan type, cell-wall sugars, or lipids of the type strain.

Growth moderate on nutrient agar; colonies are white and become yellow or lemon-yellow in 3–4 d. Obligately aerobic; weak acid production in glucose, xylose, galactose, glycerol, and cellobiose in 7 d of incubation. Catalase-positive. Growth occurs in Koser's citrate medium; ammonium salts but not nitrate are utilized as sole nitrogen source when provided with glucose as carbon + energy source. No growth on creatine, creatinine, and uric acid agar media; slight growth on nicotine agar. Gelatin and starch hydrolyzed, lecithinase produced. Cellulose not hydrolyzed. Nitrate not reduced to nitrite; urease not produced. Indole, H_2S, and acetylmethylcarbinol not produced. Good growth in 10% NaCl broth; optimum temperature between 20–37°C, no growth at 10°C. Glutamic acid is produced in a mineral salts medium when provided with a suitable carbohydrate; a pink water-soluble pigment is produced in the same medium.

Source: sewage samples in Mysore.

DNA G+C content (mol%): not determined.

Type strain: ATCC 33408, CIP 102716, JCM 11565, LMG 16219, NBRC 103060, NCIB (now NCIMB) 10583.

Sequence accession no. (16S rRNA gene): AJ617482.

Additional remarks: Stackebrandt et al. (1983b) carried out detailed study of a strain named *Arthrobacter mysorens* but unfortunately used ATCC 31021, a patent strain and not the type strain. The authors considered ATCC 31021 to be a member of the *Arthrobacter nicotianae* group of arthrobacters and to be distinct from those species now recognized.

32. **Arthrobacter nasiphocae** Collins, Hoyles, Foster, Falsen and Weiss 2002a, 571[VP]

na.si.pho'ca.e. L. masc. n. *nasus* nose; L. n. *phoca* seal; N.L. gen. n. *nasiphocae* of the nose of a seal.

The cells are Gram-stain-positive, non-spore-forming, irregular-shaped rods; coccoid forms may be observed. Colonies are circular, entire, convex, and approximately 1 mm in diameter after 24 h at 37°C on blood agar. Colonies are grayish-white in color and are nonhemolytic on blood agar. Strictly aerobic and catalase-positive. Growth is produced at 25 and 42°C. Grows in broth containing 5% NaCl but not in 10% NaCl. Acid is not produced from glucose, glycogen, lactose, mannitol, maltose, ribose, sucrose, or D-xylose. Activity is detected for alkaline phosphatase, acid phosphatase, α-glucosidase, esterase C4 (weak), phosphoamidase, pyrazinamidase, pyroglutamic acid arylamidase, and leucine arylamidase. No activity is detected for cystine arylamidase, chymotrypsin, ester lipase C8, α-fucosidase, α-galactosidase, β-galactosidase, β-glucosidase, β-glucuronidase, lipase C14, α-mannosidase, *N*-acetyl-β-glucosaminidase, valine arylamidase, urease, or trypsin. Gelatin and hippurate are hydrolyzed but esculin and starch are not. Nitrate is not reduced. Acetoin is not produced. Cell-wall murein is based on L-lysine variation A3α [type: L-Lys–L-Ala_2–Gly_{2-3}–L-Ala (Gly)]. The major menaquinones are MK-9(H_2) and MK-8(H_2).

Source: the nose of the common seal (*Phoca vitulina*).

DNA G+C content (mol%): 65.0 (HPLC).

Type strain: M597/99/10, CCUG 42953, CIP 107054, JCM 11677.

Sequence accession no. (16S rRNA gene): AJ292364.

33. **Arthrobacter nicotianae** (Giovannozzi-Sermanni 1959) Stackebrandt, Fowler, Fiedler and Seiler 1983b, 481[AL]

ni.co.tí.a'na.e. N.L. n. *Nicotiana* a scientific generic name; N.L. gen. n. *nicotianae* of *Nicotiana*, of the tobacco plant.

Growth of the type strain on agar is bright lemon-yellow. The type strain gives abundant growth on nicotine agar: the medium becomes blue at first and deep wine-red later. Nutritionally nonexacting: growth occurs in a suitable mineral salts medium with an ammonium salt as sole nitrogen source (type strain). Nicotine is utilized by the type strain as a sole or major carbon + energy source. More than 70% of the *Arthrobacter nicotianae* strains assimilate 4-amino-butyrate, 5-amino-valerate, 4-hydroxybenzoate, L-leucine, L-asparagine, D-xylose, D-ribose, L-arabinose, D-galactose, 2,3-butylenglycol, and glycerol; hydrolyze starch and casein; grow in 7% NaCl. The type strain is positive for nitrate reduction, pyrazinamidase, alkaline phosphatase, and pyrrolidonyl arylamidase and assimilates amygdalin, arbutin, cellobiose, D-arbitol, D-xylose, galactose, glycerol, L-arabinose, maltose, ribose, salicin, starch, β-gentiobiose, and glucose. It is negative for β-galactosidase, urease, and cystine arylamidase and cannot assimilate D-mannose, D-turanose, inositol, mannitol, melibiose, rhamnose, sucrose, trehalose, xylitol, *N*-acetylglucosamine, 5-ketogluconate, and phenylacetate (Margesin et al., 2004; Osorio et al., 1999).

The peptide subunit of the peptidoglycan consists of alanine, D-glutamic acid, and lysine. The interpeptide bridge contains L-alanine and D-glutamic acid (Lys–Ala–Glu type, variation A4α; Fiedler et al., 1970). Cell wall (only the type strain is tested) contains galactose and small amounts of glucose. The long-chain fatty acids are primarily of the iso, anteiso, straight chain, and unsaturated acid types, with the anteiso 12-methyl tetradecanoic acid ($C_{15:0}$ anteiso) predominating. The major respiratory isoprenoid quinones are unsaturated menaquinones with 8 and 9 isoprene units. Polar lipids consist of diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), and unidentified glycolipids. The type strain contains diglycosyldiacylglycerol with the chromatographic mobility of dimannosyldiacylglycerol (Collins and Kroppenstedt, 1983).

Source: soil and sewage.

DNA G+C content (mol%): 60.0–66.0 (T_m).

Type strain: AS 1.1895, ATCC 15236, CCM 1648, BCRC (formerly CCRC) 11219, CCUG 23842, CDA 883, CIP 82.107, DSM 20123, HAMBI 1859, IAM 12342, NBRC 14234, IMET 10353, JCM 1333, LMG 16305, NCIMB 9458, NRIC 0153.

Sequence accession no. (16S rRNA gene): X80739.

Additional remarks: in DNA–DNA hybridization studies, Stackebrandt et al. (1983b) found reassociation values of 81–93% between the type strain of *Arthrobacter nicotianae* and the following strains: "*Arthrobacter nucleogenes*" ATCC 21279, *Arthrobacter* sp. NCIB 9863, *Brevibacterium* sp. AJ 1486, and *Corynebacterium liquefaciens* ATCC 14929. Accordingly they considered that all five strains belong to the same species, *Arthrobacter nicotinae.*

After continuously decreasing oxygen tension in the growth medium, the type of *Arthrobacter nicotianae* is able to grow in the presence of nitrate carrying out anaerobic respiratory nitrate reduction (Eschbach et al., 2003).

34. **Arthrobacter nicotinovorans** Kodama, Yamamoto, Amano and Amachi 1992, 237[VP]

ni.co.ti.no.vo′rans N.L. n. *nicotinum* nicotine; L. part. adj. *vorans* devouring, destroying; N.L. part. adj. *nicotinovorans* nicotine devouring.

Aerobic, Gram-stain-positive, not acid-fast. Cells exhibit a marked rod–coccus growth cycle in complex media. The rods are motile by means of a few lateral flagella. Slight growth occurs in the presence of 10% NaCl. Starch is hydrolyzed, and nitrate is not reduced. Nicotine blue is produced from nicotine. Urea is formed from creatine and uric acid. Utilizes L-arabinose, D-galactose, D-glucose, *meso*-inositol, D-ribose, D-xylose, 4-aminobutyrate, L-arginine, L-asparagine, L-histidine, and ρ-hydroxybenzoate but not L-leucine. Citric, formic, malonic, uric, and propionic acids are assimilated but glutaric, adipic, pimelic, and benzoic acids are not. The cell-wall peptidoglycan is of the Lys–Ala–Thr–Ala type and the principal isoprenoid quinone is MK-9(H_2). The fatty acids are mainly straight chain, anteiso- and iso-methyl-branched acids. The major fatty acids are $C_{15:0}$ and $C_{17:0}$ anteiso acids.

DNA G+C content (mol%): 62.4 (HPLC).

Type strain: ATCC 49919, CIP 106990, DSM 420, NBRC 15511, JCM 3874, LMG 16253, VKM Ac-1988.

Sequence accession no. (16S rRNA gene): X80743.

Sequence accession no. (recA): AF214788.

Additional remarks: Arthrobacter oxydans DSM 420 was reclassified as *Arthrobacter nicotinovorans.*

35. **Arthrobacter niigatensis** Ding, Hirose and Yokota 2009, 858[VP]

ni.i.ga.ten′sis. N.L. masc. adj. *niigatensis* of or pertaining to the Niigata region, Japan.

Cells are nonmotile and non-spore-forming. Gram-stain positive, catalase-positive, oxidase-negative, shows a rod–coccus growth cycle, and produces non-fluorescent pigment. Growth occurs on nutrient broth agar at 5–40°C, and optimal temperature for growth is 30°C. Grows in the presence of 3–7% (w/v) NaCl. The pH range for growth is 6–11 and the optimum pH is 7.5. Colonies are round, convex, glossy, with entire margins and are light gray or light yellow. Using the API CORYNE system, a positive reaction is observed for reduction of nitrate, activities of pyrazinamidase, pyrrolidonyl arylamidase, and urease, hydrolysis of gelatin, and for the utilization of glucose, ribose, lactose, and sucrose. Maltose is not utilized and mannitol, xylose, and glycogen are weakly utilized. Using the API ZYM system, activity is detected for alkaline phosphatase, acid phosphatase, leucine arylamidase, trypsin, naphthol-AS-BI-phosphohydrolase, esterase C4, esterase lipase C8, β-galactosidase, β-glucuronidase, α-glucosidase, β-glucosidase, and α-mannosidase. No activity is detected for lipase C14, α-galactosidase, *N*-acetyl-β-glucosaminidase, α-chymotrypsin, or α-fucosidase. Activities of valine arylamidase and cystine arylamidase are weak. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$ iso. The diamino acid of the cell-wall peptidoglycan is lysine and major components are lysine, serine, threonine, and alanine. Menaquinones are MK-9(H_2) (64%), MK-8(H_2) (17%), and MK-8(H_4) (15%).

Source: a filtration substrate made from volcanic rock from Niigata, Japan.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: LC4, CCTCC AB 206012, IAM 15382, JCM 21826.

Sequence accession no. (16S rRNA gene): AB248526.

36. **Arthrobacter nitroguajacolicus** Kotoučková, Schumann, Durnová, Spröer, Sedláček, Neča, Zdráhal and Němec 2004, 776[VP]

ni.tro.gu.a.ja.co′li.cus. N.L. masc. adj. *nitroguajacolicus* pertaining to the chemical nitroguaiacol, whose name is based on N.L. *guaiacum* from Spanish guayaco, a tropical American tree and the resin derived thereof.

Cells are Gram-stain-positive irregular rods, club-shaped with typical V-forms, motile, and non-acid-fast. They display a rod–coccus life cycle. Cocci are 0.7–1 µm in diameter; rods are 0.6–1.0 µm wide and 1.0–4 µm long. Spores are not formed. Colonies are yellow, circular, convex, and opaque. Growth occurs with a suitable carbon source in mineral salts medium; no additional growth factors are required. Obligately aerobic. Growth at 4–37°C, with optimum at 25–30°C. Growth occurs in the pH range 6.0–8.0 and in the presence of up to 6% (w/v) NaCl. Catalase- and oxidase-positive. Nitrate not reduced. Methyl red test, urease, and hemolysis negative. Hydrolyzes gelatin, starch, casein, esculin, *o*-nitrophenyl-β-D-galactopyranoside, and tyrosine are hydrolyzed. Tween 80, DNA, and lecithin are not hydrolyzed. Elastase is produced. Pyrrolidonyl arylamidase and arginine dihydrolase are not produced. Production of alkaline phosphatase, acid phosphatase, α-galactosidase, and α-fucosidase is variable between strains: the type strain shows positive reactions. Simmons' citrate is utilized, but not gluconate. Acid is not produced from ribose, mannitol, sorbitol, lactose, trehalose, raffinose, sucrose, L-arabinose, D-arabitol, cyclodextrin, glycogen, pullulan, maltose, melibiose, melezitose, methyl-β-D-glucopyranoside, or tagatose. In the Biolog test system, the following compounds are utilized for respiration: dextrin, glycogen, arbutin, D-cellobiose, D-fructose, D-galactose, α-D-glucose, maltose, maltotriose, D-mannitol, D-mannose, palatinose, D-psicose, D-raffinose, D-ribose, D-sorbitol, sucrose, turanose, acetic acid, α-hydroxybutyric

acid, β-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, L-malic acid, methyl pyruvate, propionic acid, pyruvic acid, alaninamide, D-alanine, L-alanine, L-alanyl-glycine, L-asparagine, L-glutamic acid, glycyl-L-glutamic acid, L-pyroglutamic acid, L-serine, putrescine, and glycerol. Utilization of gentiobiose, α-ketoglutaric acid and β-ketoglutaric acid is strain dependent: the type strain is positive. A negative reaction is seen with α-cyclodextrin, β-cyclodextrin, inulin, mannan, Tween 40, Tween 80, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, L-arabinose, D-arabitol, L-fucose, D-galacturonic acid, α-D-lactose, lactulose, D-melezitose, D-melibiose, methyl-α-D-galactoside, methyl-β-D-galactoside, 3-methylglucose, methyl-α-D-glucoside, methyl-β-D-glucoside, methyl-α-D-mannoside, L-rhamnose, salicin, sedoheptulosan, D-tagatose, D-trehalose, xylitol, D-xylose, γ-hydroxybutyric acid, lactamide, D-lactic acid methyl ester, D-malic acid, monomethyl succinate, succinamic acid, succinic acid, *N*-acetyl glutamic acid, 2,3-butanediol, adenosine, 2-deoxyadenosine, inosine, thymidine, uridine, adenosine 5′-monophosphate, thymidine 5′-monophosphate, uridine 5′-monophosphate, fructose 6-phosphate, glucose 1-phosphate, glucose 6-phosphate, and DL-α-glycerol phosphate. The cell-wall diamino acid is lysine. The peptidoglycan type is A3α, with an Ala–Thr–Ala interpeptide bridge. The major menaquinone is MK-9(H_2); MK-8(H_2) and MK-10(H_2) occur as minor components. The cellular fatty acid pattern is dominated by $C_{15:0}$ anteiso (65–70%).

Source: forest soil.

DNA G+C content (mol%): 61.9 (HPLC).

Type strain: G2-1, CCM 4924, DSM 15232, JCM 14115.

Other strains: CCM 4925, CCM 7049.

Sequence accession no. (16S rRNA gene): AJ512504.

37. **Arthrobacter oryzae** Kageyama, Morisaki, Ōmura and Takahashi 2008, 55[VP]

o.ry′za.e. L. gen. n. *oryzae* of rice.

Cells have a rod–coccus cycle. Gram-stain-positive, motile by flagella and aerobic. Colonies are cream colored on YD agar. Growth occurs on YD agar at initial pH values between 6 and 11 and at temperatures between 4 and 34°C. In YD agar medium, up to 2% NaCl is tolerated. D-Glucose, raffinose, melibiose, D-mannitol, L-inositol, and sucrose are assimilated, but L-arabinose and cellulose are not. Leucine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-glucuronidase, and α-glucosidase are detected by the API ZYM enzyme assay; the assay is negative for alkaline phosphatase, esterase lipase (C8), trypsin, chymotrypsin, α-galactosidase, β-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Weak reactions are detected for esterase (C4), lipase (C14), valine arylamidase, and cystine arylamidase. Nitrate reductase, pyrrolidonyl arylamidase, and catalase are detected by the API Coryne enzyme assay, but urease is negative. The diagnostic diamino acid of the peptidoglycan is lysine. The acyl type of the peptidoglycan is acetyl. The major menaquinone is MK-9(H_2). The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{15:0}$ iso. Cell-wall sugars contain galactose and glucose.

Source: paddy soil, Japan.

DNA G+C content (mol%): 67.0 (HPLC).

Type strain: KV-651, JCM 15922, NBRC 102055, NRRL B-24478.

Sequence accession no. (16S rRNA gene): AB279889.

38. **Arthrobacter oxydans** Sguros 1954, 21[AL]

o.xy′dans. N.L. part. adj. *oxydans* oxidizing.

Nonmotile (only type strain investigated; Kodama et al., 1992; Li et al., 2004c). Colonies on yeast extract-peptone media are either pearl-gray/white or show a yellow, nondiffusible pigment depending on strain. Growth on nicotine-mineral salts-yeast extract agar is abundant with production of a deep blue, diffusible pigment which turns reddish or yellow-brown in older cultures. When supplied with biotin, growth occurs in a suitable mineral salts medium with an ammonium salt as nitrogen source and glucose as carbon and energy source (Keddie et al., 1986). Starch is hydrolyzed, nitrate is reduced, grows in 10% NaCl. Nicotine blue is produced from nicotine. Esculin is not hydrolyzed. Utilizes L-arginine, L-asparagine, L-histidine, L-leucine, L-arabinose, D-galactose, D-glucose, L-rhamnose, D-ribose, D-xylose, butanediol, histidinol, inositol, malonate, sorbitol, lactose, xylitol, and sucrose but not maltose. Assimilates citric acid, formic acid, propionic acid, and uric acid but not adipic acid, benzoic acid, glutaric acid, malonic acid, or pimelic acid. Urea is formed from creatinine and uric acid. Gelatin and tyrosine are hydrolyzed. Positive for DNase, citrate, β-galactosidase, and α-glucosidase and negative for pyrrolidonyl peptidase and *N*-acetylglucosaminidase. Acid is formed from glucose (Wauters et al., 2000a). Wauters et al. (2000a) described the formation of acid from mannitol, while Li et al. (2004c) showed that the type strain of *Arthrobacter oxydans* does not utilize mannitol. The cell-wall peptidoglycan is of the Lys–Ser–Thr–Ala type (A3α). The whole-cell sugars are galactose and glucose. The principal isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986). The predominant fatty acid is $C_{15:0}$ anteiso (~45%), followed by $C_{17:0}$ anteiso (~17%), $C_{16:0}$ iso (~11%), $C_{16:0}$ (~11%), and $C_{15:0}$ iso (~9%) (only type strain investigated; Kodama et al., 1992).

Source: cured tobacco leaves and associated air. Isolated by enrichment in nicotine-mineral salts-yeast extract medium.

DNA G+C content (mol%): 62.7–64.4 (T_m).

Type strain: AS 1.1925, ATCC 14358, BCRC (formerly CCRC) 11573, CCUG 17757, CIP 107005, DSM 20119, HAMBI 1857, NBRC 12138, IMET 10684, JCM 2521, LMG 3816, NCIMB 9333, NRIC 0154, VKM Ac-1114.

Sequence accession no. (recA): AF214789.

39. **Arthrobacter parietis** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1462[VP]

pa.ri′e.tis. L. gen. n. *parietis* of a wall.

Cells are Gram-stain-positive, short rods and cocci (diameter 0.8–1 µm) occurring in pairs or clusters. They are nonmotile and do not form endospores. Colonies on NA after 48 h are 1–2 mm in diameter, yellow-orange, round with entire margins, of low convexity, opaque, and smooth. No growth in an anaerobic chamber on NA. Optimal temperature for growth is 22–30°C. No or only weak growth at 37°C and no growth at 45°C. Good growth after 1 week at 4°C. Growth on medium with 15% NaCl. Growth occurs at pH

6–9, with an optimum of 7–8. Catalase-positive and oxidase-negative. Using the API CORYNE system, positive reactions are observed for nitrate reduction, pyrazinamidase, β-galactosidase, α-glucosidase, esculin (β-glucosidase), gelatinase, and fermentation of glucose. Negative reactions are obtained for alkaline phosphatase, β-glucuronidase, *N*-acetyl-β-glucosaminidase and fermentation of ribose, xylose, mannitol, and glycogen. Variable reactions are obtained for pyrrolidonyl arylamidase, urease, and fermentation of maltose, lactose, and sucrose. Using the API ZYM system, activity is detected for acid phosphatase (weak), esterase C4, leucine arylamidase, trypsin, phosphoamidase (weak), α-galactosidase, β-galactosidase, and α-glucosidase. No activity is detected for alkaline phosphatase, esterase lipase C8, lipase C14, valine arylamidase, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase. Variable results (if positive, weak) were obtained for cystine arylamidase, β-glucosidase, and α-mannosidase. The type strain is negative for the variable characters listed above. Predominant fatty acids are $C_{15:0}$ anteiso (51%) and $C_{15:0}$ iso (29%). The peptidoglycan type is A3α Lys–Thr–Ala_2. MK-9(H_2) (69%) and MK-10(H_2) (20%) are the predominant menaquinones, while MK-8(H_2) and MK-11(H_2) occur in only small amounts. The cell-wall sugar is galactose. Polar lipids of the type strain are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and two unknown glycolipids.

40. **Arthrobacter pascens** Lochhead and Burton 1953, 7[AL]

pas′cens. L. part adj. *pascens* nourishing.

Colonies on yeast-peptone medium show no distinctive pigmentation. Nutritionally nonexacting: growth occurs in a suitable mineral salts medium with an ammonium salt or nitrate as sole nitrogen source and glucose as carbon + energy source. Starch is hydrolyzed, nicotine is not utilized. Nonmotile. The cell-wall peptidoglycan is of the Lys–Ala_2 type (A3α) (Fiedler et al., 1970). The whole-cell sugars are galactose and glucose. The principal isoprenoid quinone is MK-9(H_2). The predominant fatty acid is $C_{15:0}$ anteiso (59%), followed by $C_{17:0}$ anteiso (13%), $C_{15:0}$ iso (6%), $C_{16:0}$ iso (3%), $C_{16:0}$ (3%), $C_{16:1}$ ω7*c* (3%), and $C_{18:1}$ ω9*c* (2%) (Funke et al., 1996).

Sequence accession no. (16S rRNA gene): X80740.

Sequence accession no. (recA): AF214789.

41. **Arthrobacter phenanthrenivorans** Kallimanis, Kavakiotis, Perisynakis, Spröer, Pukall, Drainas and Koukkou 2009, 278[VP]

phe.nan.thre.ni.vo′rans. N.L. n. *phenanthrenum* phenanthrene; L. v. *vorare* to devour; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *phenanthrenivorans* digesting phenanthrene.

Cells are aerobic and nonmotile, stain Gram positive, and exhibit a rod–coccus growth cycle. Colonies are cream to yellow in color. Grows at 4–37°C in mineral salts medium with a suitable carbon source; optimum growth occurs between 30 and 37°C. No additional growth factors are required. Catalase- and amylase-positive. Reduces nitrate to nitrite. Negative for oxidase, urease, lipase, and gelatinase. Does not produce H_2S. Acid is not produced from glucose, lactose, or sucrose. Utilizes phenanthrene and anthracene as sole carbon sources. The polar lipid pattern consists of phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol. The major menaquinone is MK-8 and the major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{15:0}$ iso, $C_{16:0}$, and $C_{17:0}$ anteiso.

Type strain: Sphe3, DSM 18606, JCM 16027, LMG 23796.

Sequence accession no. (16S rRNA gene): AM176541.

Sequence accession no. (recA): AM931439.

42. **Arthrobacter pigmenti** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1462[VP]

pig.men′ti. L. gen. n. *pigmenti* of pigment or paint.

Cells are Gram-stain-positive, short rods and cocci (diameter 0.8–1 µm) occurring in pairs, chains, or clusters. They are nonmotile and do not form endospores. Colonies on NA after 48 h are small (<1 mm), light yellow, round with entire margins, of low convexity, opaque, and smooth. No growth in an anaerobic chamber on NA. Optimum temperature for growth is 22–30°C. No or only weak growth at 37 or 10°C. No growth at 45 or 4°C. Growth on medium with 15% NaCl; optimal growth at 10% NaCl. Grows at pH 7–10 and optimally at pH 8–9. Catalase-positive and oxidase-negative. Using the API CORYNE system, positive reactions are observed for pyrazinamidase, β-glucuronidase, β-galactosidase, α-glucosidase, and gelatinase. Negative reactions are obtained for pyrrolidonyl arylamidase, *N*-acetyl-β-glucosaminidase, urease, and fermentation of ribose, xylose, mannitol, lactose, and glycogen. Variable reactions are obtained for nitrate reduction, esculin (β-glucosidase) and fermentation of glucose, maltose, and sucrose. Using the API ZYM system, activity is detected for alkaline phosphatase, esterase lipase C8 (weak), leucine arylamidase, trypsin, phosphoamidase (weak), α-galactosidase (weak), and β-glucuronidase. No activity is detected for lipase C14, valine arylamidase, cystine arylamidase, chymotrypsin, α-galactosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. Variable results (if positive, weak) were obtained for esterase C4, acid phosphatase, and α-mannosidase. Predominant fatty acids are $C_{15:0}$ iso (48%) and $C_{15:0}$ anteiso (40%). The peptidoglycan type is A3α Lys–Ala_4. MK-9(H_2) (66%), MK-10(H_2) (13%), and MK-7(H_2) (14%) are the predominant menaquinones, while MK-9 occurs in only small amounts. The cell-wall sugars are galactose and rhamnose. Polar lipids of the type strain are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, one unknown phospholipid, and one unknown glycolipid.

Source: a rosy biofilm overgrowing a mural painting in the Saint-Catherine chapel (castle of Herberstein, Austria).

DNA G+C content (mol%): 61.6 (HPLC).

Type strain: DSM 16403, JCM 21771, LMG 22284.

Sequence accession no. (16S rRNA gene): AJ639827.

43. **Arthrobacter polychromogenes** Schippers-Lammertse, Muijsers and Klatser-Oedekerk 1963, 2[AL]

po.ly.chro.mo′ge.nes. Gr. adj. *polu* many; Gr. n. *chroma* color; Gr. v. *gennaio* produce; N.L. part. adj. *polychromogenes* producing many colors.

Cells are nonmotile, long rods and cocci. On nutrient agar, colonies are white, circular, smooth, convex, with an entire edge. Colonies are blue colored on peptone-glucose agar due to large amounts of blue-black crystals in the colonies. Gelatin and starch are hydrolyzed. Negative for indole production, hydrogen sulfide production, acetoin production, and urease. Little or no acid from sugars. Acid from glycerol. Nitrate is reduced to nitrite. Nicotine blue is not produced from nicotine. Utilizes L-arginine, L-asparagine, L-histidine, L-leucine, L-arabinose, D-galactose, D-glucose, L-rhamnose, D-ribose, D-xylose, butanediol, and malonate but not inositol. Assimilates citric acid, formic acid, propionic acid, and uric acid but not adipic acid, benzoic acid, glutaric acid, malonic acid, or pimelic acid (Kodama et al., 1992).

Ammonium or nitrate without biotin is not sufficient as nitrogen source. Sodium citrate is sufficient as sole carbon source, also in the absence of biotin. Excellent growth and much pigment is obtained on a medium of peptone 1%, glycerol 2%, KCl 0.6%, agar 2%, pH 9.0. The bacterium also grows well, though is colorless, when vitamin-free Casamino acids are substituted for peptone in the last mentioned medium; the bacterium does not need vitamins for growth. The color appears in the vitamin-free medium after addition of biotin; biotin is necessary for the formation of the pigments. The temperature optimum for growth and pigment production is about 25°C. Most often growth but no color is observed at 37°C. Growth at 10°C but not at 41°C. A colorless culture, grown at 37°C, soon becomes colored at room temperature. At a pH of about 5, no growth occurs. Optimum pigment formation occurs at the rather high pH value of 9–10. The maximum pH for growth and pigment production is 11 or above. No pigment formation at a pH below 6. The cell-wall peptidoglycan is of the Lys–Ser–Thr–Ala type (A3α) (Fiedler et al., 1970). The whole-cell sugar is galactose. The principal isoprenoid quinone is MK-9(H_2). The predominant fatty acid is $C_{15:0}$ anteiso (~44%), followed by $C_{17:0}$ anteiso (~25%), $C_{16:0}$ iso (~6%), $C_{16:0}$ (~13%), $C_{16:0}$ iso (~6%), and $C_{15:0}$ iso (~3%) (Huang et al., 2005b; Kodama et al., 1992).

Source: air.

DNA G+C content (mol%): 62.9 (T_m; Kodama et al., 1992).

Type strain: ATCC 15216, CIP 106989, DSM 20136, NBRC 15512, JCM 2523, LMG 3821, VKM Ac-1955.

Sequence accession no. (16S rRNA gene): X80741.

44. **Arthrobacter protophormiae** (*ex* Lysenko 1959) Stackebrandt, Fowler, Fiedler and Seiler 1984, 270[VP] (Effective publication: Stackebrandt, Fowler, Fiedler and Seiler 1983b, 482.)

pro.to.phor.mi′a.e. N.L. n. *Protophormia* a genus of dipteran insects, N.L. gen. n. *protophormiae* of *Protophormia*.

In 1-d-old cultures, the cells are slightly club-shaped rods with rounded ends (0.6–0.8 × 0.8–2.0 μm) occurring singly or in irregular groups. Stationary-phase cultures (older than 2 d) are composed almost entirely of spherical cells only. Colonies on nutrient agar show a pale to sulfur yellow, nondiffusible pigment. The peptide subunit of the peptidoglycan consists of alanine, D-glutamic acid, and lysine. The interpeptide bridge contains alanine and glutamic acid (Lys–Ala–Glu type, variation A4α).

Cell wall (only the type strain is tested) contains galactose and small amounts of glucose. The long-chain fatty acids are primarily of the iso, anteiso, straight chain, and unsaturated types, with the anteiso 12-methyl tetradecanoic acid ($C_{15:0}$ anteiso) predominating. The major respiratory isoprenoid quinones are unsaturated menaquinones with 8 and 9 isoprene units (MK-8 and MK-9). Polar lipids consist of diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), and unidentified glycolipids. More than 80% of the 6 strains of *Arthrobacter protophormiae* strains assimilate 5-amino-valerate, 4-hydroxybenzoate, L-asparagine, L-arginine, L-histidine, L-arabinose, D-galactose, and glycerol; resistant to 7% NaCl.

45. **Arthrobacter psychrochitiniphilus** Wang, Gai, Chen and Xiao 2009, 2761[VP]

psy.chro.chi.ti.ni′phi.lus. Gr. adj. *psuchros* cold; N.L. n. *chitinum* chitin; Gr. adj. *philos* loving; N.L. masc. adj. *psychrochitiniphilus* a cold, chitin-loving bacterium.

Individual cells show a distinct rod–coccus cycle. Cells are Gram-stain-positive, aerobic, catalase-positive, and oxidase-negative motile rods. Spores or capsules are not seen. Colonies in LB medium at 20°C are yellow, circular, and convex. Growth occurs at 0–25°C, the optimal growth temperature is around 20°C. Grows well at 0–3% NaCl. Optimal growth occurs at pH 6–8. Tween 80, starch, cellulose, lactose, and chitin are hydrolyzed. Gelatin, lecithin, and urea are not hydrolyzed. Nitrate is reduced and NH_3 production is positive. Production of indole and H_2S is negative. Sensitive to ampicillin, chloramphenicol, kanamycin, streptomycin, and tetracycline. Growth occurs on lactose or chitin as the sole carbon source. The cellular fatty acid pattern is dominated by $C_{15:0}$ anteiso. The peptidoglycan type is A3α. The major menaquinone is MK-9(H_2). Biolog tests show that the following compounds are utilized for respiration: dextrin, Tween 40, Tween 80, *N*-acetyl-D-glucosamine, L-arabinose, D-arabitol, cellobiose, D-fructose, D-galactose, D-glucose, α-D-lactose, lactulose, maltose, maltotriose, D-mannitol, D-mannose, D-melezitose, melibiose, methyl-β-D-galactoside, D-psicose, D-ribose, D-sorbitol, sucrose, D-tagatose, trehalose, turanose, xylitol, D-xylose, acetic acid, α-hydroxybutyric acid, α-ketovaleric acid, D-lactic acid methyl ester, L-lactic acid, L-malic acid, pyruvic acid methyl ester, succinic acid monomethyl ester, propionic acid, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, D-alanine, L-alanyl glycine, L-asparagine, L-glutamic acid, glycyl L-glutamic acid, L-serine, putrescine, 2,3-butanediol, glycerol, adenosine, inosine, thymidine, uridine, adenosine

5′-monophosphate, thymidine 5′-monophosphate, uridine 5′-monophosphate, D-glucose 6-phosphate, and DL-α-glycerol phosphate.

Source: guano of Adelie penguins, Antarctica.

DNA G+C content (mol%): 58.5 (HPLC).

Type strain: GP3, CGMCC 1.6355, JCM 13874.

46. **Arthrobacter psychrolactophilus** Loveland-Curtze, Sheridan, Gutshall and Brechley 2000, 3[VP] (Effective publication: Loveland-Curtze, Sheridan, Gutshall and Brechley 1999, 362.)

psy.chro.lac.to′phi.lus. Gr. adj. *psuchros* cold; L. n. *lac lactis* milk; Gr. masc. adj. *philos* friend, loving; N.L. masc. adj. *psychrolactophilus* a cold, milk (sugar)-loving (bacterium).

Individual cells show a distinct rod–coccus cycle and have a mean cell length of 1.4 μm during exponential growth and 0.5 μm during stationary phase. Gram-stain-positive; easily decolorized; strict aerobe. Contains lysine as the diagnostic amino acid in the peptidoglycan. Non-spore-forming. Nonmotile. No vitamin requirements; grows in mineral salts medium with ammonium chloride as sole source of nitrogen. Colonies on trypticase soy agar without glucose are yellow; degree of pigmentation varies with growth temperature and age of the cells. Able to grow at 0–5°C. Growth range, 0–30°C. Generation time at 10°C in trypticase soy broth with no added carbohydrate is 4.8 h. Does not produce acid with glucose as carbon source. Can utilize lactose, sorbitol, melibiose, cellobiose, glycerol, maltose, raffinose, xylose, galactose, sucrose, and glucose as sole carbon sources. Produces catalase. Produces β-galactosidase, β-glucuronidase, β-glucosidase, β-glucosidase, amylase, and gelatinase. Negative for nitrate reduction, alkaline phosphatase, *N*-acetylglucosaminidase, urease, and DNase. The major cellular fatty acids are anteiso- and isobranched fatty acids. The predominant fatty acid is $C_{15:0}$ anteiso (~73%), followed by $C_{17:0}$ anteiso (~13%), $C_{16:0}$ iso (~8%), $C_{16:0}$ (~2%), and $C_{15:0}$ iso (~1.4%). All other fatty acids are at levels below 1%.

Source: soil.

DNA G+C content (mol%): 60.6 (T_m).

Type strain: B7, ATCC 700733, JCM 12399.

Sequence accession no. (16S rRNA gene): AF134179.

47. **Arthrobacter psychrophenolicus** Margesin, Schumann, Spröer and Gounot 2004, 2070[VP]

psy.chro.phe.no′li.cus. Gr. adj. *psuchros* cold; N.L. masc. adj. *phenolicus* relating to phenol; N.L. masc. adj. *psychrophenolicus* relating to phenol [degradation] at low temperatures.

On nutrient agar, colonies are round, convex, glossy, and have entire margins and a yellow, non-fluorescent pigment. Cells are Gram-stain-positive, aerobic, non-spore-forming, and nonmotile. They exhibit a rod–coccus cycle with irregular rods in the exponential growth phase and predominantly coccoid cells in the stationary growth phase. Positive for phenol degradation, nitrate reduction, and urease, but negative for alkaline phosphatase, pyrrolidonyl arylamidase, and cystine arylamidase. Hydrolyze skimmed milk at 10°C and 25°C. Can utilize mannitol and phenylacetate but not glucose or arabinose as carbon sources. Sensitive to mezlocillin, cefamandole, cefotaxime, tetracycline, amikacin, and imipenem. Good growth and phenol biodegradation occur at 1–25°C (facultative psychrophile). Fully degrades up to 10 mM phenol as the sole carbon source. No growth occurs at pH 5 or 11. The predominant fatty acid (72.1%) is $C_{15:0}$ anteiso, while $C_{17:0}$ anteiso, $C_{16:0}$ iso, $C_{15:0}$ iso, $C_{16:0}$, and $C_{14:0}$ iso are detected in small amounts. The peptidoglycan type is A4α L-Lys–L-Glu. MK-10 is the predominant menaquinone, while MK-9 and MK-11 occur in smaller amounts (ratio of peak areas 72:12:1, respectively). The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and an unidentified glycolipid. The only cell-wall sugar is glucose.

Source: an alpine ice cave in Werfen (Salzburg), Austria.

Type strain: AG31, DSM 15454, JCM 13568, LMG 21914.

Sequence accession no. (16S rRNA gene): AJ616763.

48. **Arthrobacter ramosus** Jensen 1960, 131[AL]

ra.mo′sus. L. masc. adj. *ramosus* branched, branching.

Motile by a few lateral flagella. Colonies on yeast extract-peptone media show no distinctive pigmentation. Nutritionally nonexacting: growth occurs in a suitable mineral salts medium with an ammonium salt or nitrate as sole nitrogen source. Starch is not hydrolyzed, and nicotine is not utilized.

The cell-wall peptidoglycan is of the Lys–Ala_4 type (A3α). The whole-cell sugars are galactose, rhamnose, and mannose. The principal isoprenoid quinone is MK-9(H_2) (Keddie et al., 1986) Major fatty acids are $C_{15:0}$ anteiso (63%), $C_{17:0}$ anteiso (8%), and $C_{15:0}$ iso (6%) (Funke et al. 1996).

Sequence accession no. (16S rRNA gene): X80742.

49. **Arthrobacter rhombi** Osorio, Barja, Hutson and Collins 1999, 1220[VP]

rhom′bi. L. masc. n. *rhombus* flatfish; L. gen. n. *rhombi* of flatfish.

Cells are Gram-stain-positive, short rods and cocci. They are non-spore-forming and nonmotile. On BHA, smooth convex colonies which are yellowish or whitish in color and with a diameter of approximately 1 mm are formed after 48 h. Growth occurs in 1% (w/v) and 10% (w/v) NaCl and at 4 and 30°C. They are strictly aerobic and catalase- and oxidase-positive. Using the API CORYNE system, positive reactions for β-galactosidase and esculinase are observed. Negative reactions are obtained for nitrate reductase, pyrazinamidase, pyrrolidonyl arylamidase, urease, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and gelatinase. Using the API 50CH system, the following substrates are used as sole carbon sources: glycerol, galactose, D-glucose, D-fructose, D-mannose, mannitol, amygdalin, arbutin, esculin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, β-gentiobiose, D-turanose, gluconate, and D-arabitol. Erythritol, D-arabinose, L-arabinose, ribose, D-xylose, adonitol, methyl-β-xyloside, L-sorbose, dulcitol, sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, inositol, *N*-acetyl-β-glucosamine, inulin, melezitose, D-raffinose, starch, glycogen, xylitol, D-lyxose, D-tagatose, D-fucose, L-fucose, L-arabitol, 2-ketogluconate, and 5-ketogluconate are not utilized. The

cell-wall murein type is A4α (L-Lys–L-Ala–D-Glu).

Sequence accession no. (16S rRNA gene; another strain): Y15885.

50. **Arthrobacter roseus** Reddy, Prakash, Matsumoto, Stackebrandt and Shivaji 2002, 1020[VP]

ro′se.us. L. masc. adj. *roseus* rose-colored.

Rod–coccus growth cycle with irregular rods in the exponential phase and predominantly coccoid cells (~1.0 µm in diameter) in the stationary phase. Gram-stain-positive, nonspore-forming, and nonmotile; colonies on peptone/yeast extract medium are round, smooth, convex, 0.2–1 mm in diameter, and red-pigmented. Pigment is insoluble in water but soluble in methanol and exhibits four absorption maxima, at 437, 467, 494, and 524 nm. Aerobic. Growth occurs at 5–30°C and at pH 6–12, and cells tolerate up to 5.8% NaCl. Optimum growth is observed at 22°C and pH 7. Catalase, phosphatase, gelatinase, and nitrate reduction tests are positive; oxidase, urease, lipase, β-galactosidase, arginine dihydrolase, indole production, methyl red test, Voges–Proskauer test, and levan formation are negative. Esculin and starch are not hydrolyzed. Positive for utilization of mannose, galactose, maltose, fructose, glucose, arabinose, ribose, xylose, rhamnose, raffinose, trehalose, succinic acid, fumaric acid, citric acid, mannitol, sorbitol, adonitol, sucrose, inulin, pyruvate, acetate, alanine, leucine, isoleucine, valine, serine, arginine, aspartic acid, glutamic acid, asparagine, glutamine, proline, and phenylalanine. The following substrates are not utilized as sole carbon sources: dulcitol, inositol, melibiose, lactose, nicotine, cellulose, glycine, threonine, cysteine, methionine, lysine, tyrosine, histidine, and tryptophan. No acid or gas from glucose, arabinose, xylose, rhamnose, fructose, galactose, mannose, lactose, maltose, or sucrose. Sensitive to penicillin, chlortetracycline, chloramphenicol, oxytetracycline, tetracycline, erythromycin, nitrofurantoin, bacitracin, nitrofurazone, leucomycin, rifampin, nystatin, cotrimoxazole, trimethoprim, ampicillin, carbenicillin, gentamicin, amoxicillin, tobramycin, and polymyxin B but resistant to furazolidone, colistin, furoxone, and kanamycin. The peptidoglycan type is Lys–Gly–Ala_3 (variation A3α) and the major menaquinone is MK-9(H_2). Cell-wall sugars are galactose, glucose, ribose, and rhamnose. Cellular fatty acids are $C_{14:0}$ iso, $C_{14:0}$, $C_{15:0}$ iso, $C_{15:0}$ anteiso, $C_{15:0}$, $C_{16:0}$ iso, $C_{16:0}$, $C_{16:1}$, $C_{17:0}$ anteiso, $C_{18:0}$, and $C_{18:2}$. The predominant polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and an unidentified glycolipid (Busse, unpublished results).

Type strain: CMS 90r, DSM 14508, JCM 11881, MTCC 3712.

Sequence accession no. (16S rRNA gene): AJ278870.

51. **Arthrobacter russicus** Li, Kawamura, Fujiwara, Naka, Liu, Huang, Kobayashi and Ezaki 2004c, 834[VP]

rus′si.cus. N.L. masc. adj. *russicus* pertaining to Russia (Russian space station).

Grows well under aerobic conditions at 30°C on BHI agar plates, but unable to grow at 37°C. Gram-stain-positive, nonmotile, irregular rods, about 1.3–3.6 µm long and 0.5–0.9 µm wide. Circular, smooth and creamy colonies grow to a diameter of about 1.5 mm after 24 h. Positive for Tween 40, Tween 80, D-fructose, D-mannose, methyl pyruvate, L-alanyl glycine, and putrescine but negative for dextrin, arbutin, D-gluconic acid, maltose, maltotriose, D-melezitose, 3-methyl glucose, methyl-α-D-glucoside, methyl-β-D-glucoside, palatinose, D-ribose, salicin, sucrose, D-trehalose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketovaleric acid, D-lactic acid methyl ester, L-lactic acid, L-malic acid, propionic acid, succinamic acid, succinic acid, alaninamide, L-asparagine, and 2,3-butanediol, esculin hydrolysis, urease activity, and nitrate reduction. Utilizes glucose but not inositol, sorbitol, lactose, xylitol, xylose, maltose, mannitol, and sucrose. Weakly positive for monomethyl succinate and L-glutamic acid. Variable for turanose, pyruvic acid, uridine, uridine 5′ monophosphate. Cell-wall peptidoglycan is A3α Lys–Ala_2. Predominant isoprenoid quinone is MK-9(H_2). Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. Predominant polar lipids are cardiolipin and phosphatidylinositol.

Source: an air sample from the Russian space station Mir.

DNA G+C content (mol%): 65.5 (HPLC).

Type strain: DSM 14555, GTC 863, JCM 11414.

Sequence accession no. (16S rRNA gene): AB071950.

52. **Arthrobacter sanguinis** Mages, Frodl, Bernard and Funke 2008, 2985[VP]

san′gui.nis. L. masc. gen. n. *sanguinis* of blood, indicating that the bacterium was isolated from a blood culture.

The cells are coryneform bacteria without irregular branching, and spores are not formed. The organism is obligately aerobic. The colonies are whitish-grayish, slightly convex, of creamy texture, and up to 2 mm in diameter after 24 h of incubation at 35°C on Columbia SBA plates. Activities of the following enzymes are detected: catalase, acid phosphatase, alkaline phosphatase, esterase (C4), esterase lipase (C8), α-galactosidase, β-galactosidase, gelatinase, *N*-acetyl-β-glucosaminidase, α-glucosidase, leucine arylamidase, α-mannosidase, pyrazinamidase, and trypsin. Activities of α-chymotrypsin, cystine arylamidase, α-fucosidase, β-glucosidase, β-glucuronidase, lipase (C14), nitrate reductase, naphthol-AS-BI-phosphohydrolase, urease, and valine arylamidase are not observed. The bacterium is capable of utilizing *N*-acetylglucosamine, amygdalin, D-arabitol, cellobiose, fructose, galactose, gentiobiose, glucose, glycerol, maltose, mannitol, mannose, melibiose, potassium, gluconate, potassium 2-ketogluconate, raffinose, sucrose, sorbitol, trehalose, and turanose as carbon sources. The type strain did not utilize adonitol, D-arabinose, L-arabinose, L-arabitol, arbutin, dulcitol, erythritol, fucose, methyl-α-D-glucopyranoside, glycogen, inositol, inulin, potassium 5-ketogluconate, lactose, lyxose, methyl-α-D-mannopyranoside, melezitose,

rhamnose, ribose, salicin, sorbose, starch, tagatose, methyl-β-D-xylopyranoside, xylitol, or xylose. Lysine is the diamino acid of the peptidoglycan, and $C_{15:0}$ anteiso and $C_{17:0}$ anteiso are the predominant cellular fatty acids.

Source: a blood culture.

DNA G+C content (mol%): not determined.

Type strain: CCUG 46407, DSM 21259.

Sequence accession no. (16S rRNA gene): EU086805.

53. **Arthrobacter scleromae** Huang, Zhao, He, Wang, Liu, You and Guan 2005a, 1743[VP] (Effective publication: Huang, Zhao, He, Wang, Liu, You and Guan 2005b, 1453.)

scle.ro′ma.e. N.L. gen. n. *scleromae* of scleroma.

Cells are Gram-stain-positive, non-spore-forming, and nonmotile and display a rod–coccus life cycle. They are obligately aerobic, catalase-positive, and ~0.25 to ~0.35 µm in diameter. Colonies on blood agar or nutrient agar are whitish, glistening, convex, smooth surfaced, and circular. The colonies grow to up to 4 to 5 mm in size by 72 h. Growth occurs with a suitable carbon source in mineral salts medium; no additional growth factors are needed. Growth also occurs in the presence of 5% NaCl, at 15–37°C and pH 6–9, but not in 10% NaCl at 5 or 42°C. The organism hydrolyzes casein, DNA, esculin, gelatin, starch, and tyrosine but not lecithin or xanthine. The nitrate reduction test is weakly positive. *N*-Acetylglucosaminidase, β-galactosidase, α-glucosidase, lipase, pyrrolidonyl peptidase, and urease are not produced. Acid is produced from mannitol. It utilizes the following substrates as sole carbon sources: γ-aminobutyrate, L-arginine, L-asparagine, citrate, D-fructose, fumarate, D-galactose, D-gluconate, D-glucose, glycerol, L-histidine, *p*-hydroxybenzoate, 2-oxoglutarate, lactose, DL-malate, maltose, mannose, D-melezitose, phenylacetate, pyruvate, D-raffinose, salicin, sorbitol, succinate, sucrose, trehalose, D-turanose, xylitol, and D-xylose. The following substrates are not utilized: acetamide, adipate, adonitol, L-alanine, ρ-aminobenzoate, D-arabitol, arbutin, azelate, benzoate, 2,3-butanediol, *n*-butyrate, caprylate, D-cellobiose, L-citrulline, L-cysteine, dulcitol, erythritol, formate, glucosamine, D-glucuronate, glutarate, glycogen, glycolate, γ-hydroxybutyrate, inulin, DL-isoleucine, isovalerate, L-leucine, maleate, malonate, DL-methionine, α-methyl-D-glucoside, α-methyl-D-mannoside, nicotine, L-ornithine, oxalate, L-phenylalanine, *o*-phthalate, pimelate, L-rhamnose, D-ribose, sebacate, sorbose, suberate, D-tartrate, L-threonine, L-tryptophan, or DL-valine. Compounds slowly utilized are acetate, L-arabinose, inositol, mannitol, and melibiose. The strain is susceptible to ceftriaxone, chloramphenicol, rifampin, and tetracycline; moderately susceptible to cefazolin, cefotaxime, doxycycline, erythromycin, nitrofurantoin, piperacillin, and vancomycin; and resistant to amikacin, ampicillin, gentamicin, kanamycin, norfloxacin, oxacillin, penicillin G, streptomycin, and tobramycin. The major cellular fatty acid is $C_{15:0}$ anteiso, with significant amounts of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:1}$ anteiso ω9*c*, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-8(H_2). The cell-wall peptidoglycan type is L-Lys–L-Ser–L-Thr–L-Ala (A3α), and the cell-wall sugars are galactose and glucose.

Type strain: YH-2001, CGMCC 1.3601, JCM 12642.

Sequence accession no. (16S rRNA gene): AF330692.

54. **Arthrobacter soli** Roh, Sung, Nam, Chang, Kim, Yoon, Jeon, Oh and Bae 2008a, 1993[VP] (Effective publication: Roh, Sung, Nam, Chang, Kim, Yoon, Jeon, Oh and Bae 2008b, 43.)

so′li. L. neut. gen. n. *soli* of soil, the source of the type strain.

The cells are rod-shaped (0.9 × 2.0~3.0 µm), Gram-stain-positive, oxidase-positive, and catalase-negative. Colonies are yellow-pigmented and circular, measuring approximately 1.0–2.0 mm in diameter after 2 d of growth on TSBA at 30°C. The temperature range for growth is 16~40°C, but no growth occurs at 15 and 41°C. No growth occurs in NaCl at concentrations greater than 15%. Optimal pH for growth is 7.0. The strain can reduce nitrate to nitrite. Indole is not produced, and glucose fermentation does not occur. Cells are arginine dihydrolase- and urease-negative. Gelatin hydrolysis occurs, but not esculin and PNPG (*p*-nitrophenyl α-D-glucopyranoside) hydrolysis. Potassium gluconate, malate, trisodium citrate, phenylacetic acid, glycerol, L-arabinose, D-ribose, D-adonitol, methyl-β-D-xyloside, D-galactose, D-glucose, D-fructose, D-mannose, *N*-acetylglucosamine, D-cellobiose, D-maltose, D-lactose, gluconate, 2-ketogluconate, and 5-ketogluconate are assimilated; capric acid, adipic acid, erythritol, D-arabinose, D-xylose, L-xylose, L-sorbose, L-rhamnose, dulcitol, inositol, D-mannitol, D-sorbitol, methyl-α-D-mannoside, methyl-α-D-glucoside, amygdalin, arbutin, esculin, salicin, D-melibiose, sucrose, D-trehalose, inulin, D-melezitose, D-raffinose, starch, glycogen, xylitol, gentiobiose, D-turanose, D-lyxose, D-tagatose, D-fucose, L-fucose, D-arabitol, and L-arabitol are not assimilated. Cells are positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-glucosidase, and α-mannosidase. However, cells are negative for α-chymotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase. The predominant fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso.

Source: wastewater reservoir sediment collected in Daejeon, Republic of Korea.

DNA G+C content (mol%): 62.0 (HPLC).

Type strain: SYB2, DSM 19449, KCTC 19291.

Sequence accession no. (16S rRNA gene): EF660748.

55. **Arthrobacter stackebrandtii** Tvrzová, Schumann, Spröer, Sedláček, Verbarg, Kroppenstedt and Páčová 2005b, 807[VP]

sta.cke.brand′ti.i. N.L. gen. masc. n. *stackebrandtii* of Stackebrandt, named in honor of Erko Stackebrandt for his pioneering contributions to our insight into the phylogenetic structure of the suborder *Micrococcineae* and of the genus *Arthrobacter* in particular.

Cells are irregular club-shaped rods showing a rod–coccus cycle, 0.6–1 × 1–3 µm, occurring in pairs as typical V-forms. Gram-stain-positive, nonmotile, non-acid-fast, and non-spore-forming. Growth occurs at 4–30°C. Growth occurs at pH 5.7–9.1 and in the presence of 5% NaCl. Obligately aerobic. Positive for catalase, urease, and pyrazinamidase. Negative for oxidase, β-glucuronidase, β-galactosidase,

α-glucosidase, *N*-acetyl-β-glucosaminidase, and pyrrolidonyl arylamidase. Nitrate is reduced to nitrite. Nitrite is not reduced; Tween 80 and esculin are not hydrolyzed. Starch and gelatin are hydrolyzed. Acid production is negative from glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen. The following compounds are utilized (Biolog system): α-cyclodextrin, dextrin, Tween 40, L-arabinose, D-arabitol, arbutin, D-cellobiose, D-fructose, L-fucose, D-galactose, α-D-glucose, α-D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melibiose, methyl-α-D-galactoside, methyl-β-D-galactoside, palatinose, D-psicose, D-raffinose, D-ribose, salicin, stachyose, sucrose, D-trehalose, turanose, D-xylose, β-ketovaleric acid, methyl pyruvate, pyruvic acid, L-asparagine, glycerol, adenosine, inosine, thymidine, and uridine. Negative reactions (Biolog) were observed with β-cyclodextrin, glycogen, inulin, mannan, Tween 80, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, D-galacturonic acid, gentiobiose, D-gluconic acid, *meso*-inositol, D-melezitose, 3-methyl glucose, methyl-α-D-glucoside, methyl-β-D-glucoside, methyl-α-D-mannoside, L-rhamnose, sedoheptulosan, D-sorbitol, xylitol, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, lactamide, D-lactic acid methyl ester, D-malic acid, monomethyl succinate, propionic acid, succinamic acid, succinic acid, *N*-acetylglutamic acid, alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-glutamic acid, glycyl L-glutamic acid, L-pyroglutamic acid, putrescine, 2,3-butanediol, adenosine 5′-monophosphate, uridine 5′-monophosphate, fructose 6-phosphate, glucose 1-phosphate, glucose 6-phosphate, and DL-glycerophosphate. The cellular fatty acid contents of $C_{15:0}$ anteiso (48.1%), $C_{17:0}$ anteiso (14.4%), $C_{14:0}$ iso (1.84%), $C_{15:0}$ iso (14.2%), $C_{16:0}$ iso (16.0%), $C_{17:0}$ iso (3.5%), and $C_{16:0}$ (1.4%). The peptidoglycan type is A3α Lys–Ala_2. Strain CCM 2783^T possesses predominantly menaquinone MK-9(H_2) (62%) and MK-10(H_2) (25%) and a small amount of MK-11(H_2) (5%).

Sequence accession no. (16S rRNA gene): AJ640198.

56. **Arthrobacter subterraneus** Chang, Bae, Nam, Kwon, Park, Shin, Kim, Quan, Rhee, An and Park, 2008, 1993^{VP} (Effective publication: Chang, Bae, Nam, Kwon, Park, Shin, Kim, Quan, Rhee, An and Park 2007, 1878.)

sub.ter.ra′ne.us. L. masc. adj. *subterraneus* under the earth, indicating the source of isolation.

The cells are Gram-stain-positive, short rods, and cocci (diameter 0.8–1 µm) occurring singly, in pairs, or in clusters. They are nonmotile and do not form endospores. Colonies grown on NA after 48 h are small (<1 mm), pale yellow, round with entire margins, of a low convexity, opaque, and smooth. Do not grow in an anaerobic chamber on NA. Optimum temperature for growth is 20–30°C. Weak growth at 37°C, and no growth at 45°C. Growth is apparent at 4°C after 1 week of incubation. Growth occurs on media with 13% NaCl, yet not with 15% NaCl. Grows at pH 5.3–10.5. Catalase-positive and oxidase-negative. Using the API STAPH system, positive reactions are observed for fermentation with D-mannitol, xylitol, D-melibiose, and raffinose, whereas negative reactions are obtained for fermentation with D-glucose, D-fructose, D-mannose, maltose, lactose, D-trehalose, potassium nitrate, β-naphthyl-acid phosphatase, sodium pyruvate, xylose, sucrose, α-methyl-D-glucoside, *N*-acetylglucosamine, arginine, and urea. Using the API ZYM system, activity is detected with esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, trypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, and α-glucosidase, whereas no activity is detected with alkaline phosphatase, lipase (14), cystine arylamidase, α-chymotrypsin, α-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. The predominant fatty acids are $C_{15:0}$ anteiso (35%) and $C_{17:1}$ anteiso ω9*c* (15%). The cell-wall peptidoglycan type is A3α, with a Lys–Thr–Ala_3 interpeptide bridge. The major menaquinone is MK-9(H_2). The cell-wall sugars are galactose, glucose, and ribose.

57. **Arthrobacter sulfonivorans** Borodina, Kelly, Schumann, Rainey, Ward-Rainey and Wood 2002a, 685^{VP} (Effective publication: Borodina, Kelly, Schumann, Rainey, Ward-Rainey and Wood 2002b, 180.)

sul.fo.ni.vo′rans. N.L. n. *sulfonum* sulfone group, L. v. *vorare* to devour, N.L. part. adj. *sulfonivorans* sulfone-devouring.

Cells are spherical, 0.7 µm in diameter. Gram-stain-positive, forming clumps and chains in liquid culture; motile; spores or capsules not seen; catalase- and oxidase-positive. Grows heterotrophically and aerobically on glucose, fructose, sucrose, galactose, acetate, ethanol, pyruvate, malate, succinate, citrate, serine, alanine, taurine, diethylsulfone, and yeast extract. Grows aerobically on methylated sulfur compounds (dimethylsulfone, dimethylsulfoxide, and dimethylsulfide), methanol, methylamine, and dimethylamine. Methylotrophic growth with dimethylsulfone uses the ribulose monophosphate cycle for formaldehyde assimilation. Does not grow with trimethylamine or alkanesulfonates (methane-, propane-, butane-, pentane-, and hexane-sulfonate), or autotrophically on inorganic sulfur compounds. Nitrate is not reduced. Growth on dimethylsulfone occurs optimally at pH 7.3–7.4 and at 20–25°C. Temperature range for growth is 4–30°C with no growth at 37 or 44°C. Ammonium chloride, nitrate, and methylamine are used as nitrogen sources for growth. Growth occurs in the presence of 1.5% or 2.5% (w/v) NaCl, but not with 5% (w/v) NaCl. On dimethylsulfone-agar medium, colonies are creamy-yellow, circular-umbonate, and 0.5–0.7 mm in diameter. The principal isoprenoid quinone is MK-9(H_2), with smaller amounts of MK-10(H_2), MK-8(H_2), MK-9, MK-7(H_2), and MK-11(H_2). The principal cellular fatty acid is $C_{15:0}$ anteiso, with $C_{15:0}$ iso, $C_{16:0}$ iso and $C_{17:0}$ anteiso also present. Peptidoglycan contains lysine as the diagnostic diamino acid, as well as alanine, glutamic acid, threonine, and serine; peptidoglycan type (L-Lys–L-Ser–L-Thr–L-Ala) is A11.23.

Source: soil from the root ball of Allium aflatunense.

DNA G+C content (mol%): 61.0 (T_m).

Type strain: ALL, ATCC BAA-112, DSM 14002, JCM 13520.

Sequence accession no. (16S rRNA gene): AF235091.

58. **Arthrobacter sulfureus** Stackebrandt, Fowler, Fiedler and Seiler 1984, 270[VP] (Effective publication: Stackebrandt, Fowler, Fiedler and Seiler 1983b, 484.)

sul.fu′re.us. L. masc. adj. *sulfureus* of or like sulfur, meaning sulfur-colored.

In young cultures rod-shaped cells, irregular (0.4–0.6 × 1.2 to 1.6 μm), angular or slightly curved, and occasionally club-shaped; snapping divisions are observed. In old cultures, rods become shorter, and in some strains coccoid cells are predominant. Gram-stain-positive. Motile with peritrichous flagella or nonmotile. Colonies large, circular, smooth, entire, raised, glistening, dull, yellow, opaque, butyrous; 2–3 mm in diameter. Slightly turbid in nutrient broth; moderate growth and turbid in glutamate broth; liquefaction in nutrient gelatin stab culture. Nitrate not reduced to nitrite; indole not produced; hydrolysis of starch and casein negative; acetyl-methyl carbinol not produced; catalase-positive. No acid or gas from glycerol, xylose, glucose, sucrose, lactose, dextrin, and starch. Assimilate 4-hydroxybenzoate, L-leucine, L-asparagine, L-arginine, and L-histidine; two of three strains assimilate 5-aminovalerate, malonate, levulinate, D-ribose, D-galactose, D-xylitol, and 2,3-butylenglycol. Cellulose not attacked. The type strain is positive for pyrazinamidase and urease but negative for β-galactosidase. Assimilation of D-arabitol, inositol, maltose, mannitol, xylitol, and 5-ketogluconate, but no assimilation amygdalin, arbutin, cellobiose, D-mannose, D-turanose, D-xylose, glycerol, L-arabinose, melibiose, rhamnose, ribose, salicin, sucrose, trehalose, β-gentiobiose, and *N*-acetylglucosamine (only type strain investigated; Osorio et al., 1999). The peptide subunit consists of alanine, D-glutamic acid, and lysine. The interpeptide bridge consists of glutamic acid (Lys–Ala–Glu type, variation A4α). Cell wall (only one strain tested) contains galactose and traces of mannose. The long-chain fatty acids (two strains tested) are primarily of the iso, anteiso, straight chain, and unsaturated acid types, with the anteiso 12-methyltetradecanoic acid ($C_{15:0}$ anteiso) dominating. The major respiratory quinones are unsaturated menaquinones either with 9 or with equal amounts of 9 and 10 isoprenoic units. Polar lipids consist of diphosphatidylglycerol, phosphatidylglycerol, and of unidentified glycolipids. Optimal temperature and pH for growth are 25–30°C and 7.0–8.0. No growth at pH 5.0.

DNA G+C content (mol%): 64.5–66.0 (T_m).

Type strain: ATCC 19098, CIP 106986, DSM 20167, NBRC12678, JCM 1338, LMG 16694, NRRL B-14730.

Sequence accession no. (16S rRNA gene): X83409.

Sequence accession no. (recA): AF214787.

59. **Arthrobacter tecti** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1462[VP]

tec′ti. L. gen. n. *tecti* from the ceiling.

Cells are Gram-stain-positive, short rods and cocci (diameter 0.8–1 μm) occurring in pairs or clusters. They are nonmotile and do not form endospores. Colonies on NA after 48 h are small (<1 mm), yellow, round with entire margins, of low convexity, opaque, and smooth. No growth in an anaerobic chamber on NA. Optimum temperature for growth is 22–30°C. Growth on medium with 15% NaCl added. Growth at pH 6–9; optimal growth at pH 8. Catalase-positive and oxidase-negative. Using the API CORYNE system, a positive reaction is observed for *N*-acetyl-β-glucosaminidase. Most strains, including the type strain, test positive for gelatinase but negative for pyrrolidonyl arylamidase and fermentation of ribose and mannitol. Negative reactions are obtained for nitrate reduction, β-glucuronidase, urease, and fermentation of ribose, xylose, maltose, lactose, and glycogen. Variable reactions are obtained for pyrazinamidase, alkaline phosphatase, β-galactosidase, α-glucosidase, esculin (β-glucosidase), and fermentation of glucose and sucrose. Using the API ZYM system, activity is detected for alkaline phosphatase (weak), acid phosphatase (weak), leucine arylamidase, and phosphoamidase (weak). Most strains test positive for esterase C4, esterase lipase C8, trypsin (negative for the type strain), *N*-acetyl-β-glucosaminidase (negative for the type strain), and α-mannosidase (negative for the type strain). No activity is detected for lipase C14, valine arylamidase, cystine arylamidase, α-galactosidase, β-glucuronidase, or α-fucosidase. Variable reactions are obtained for chymotrypsin, β-galactosidase, α-glucosidase, and β-glucosidase. Predominant fatty acids are $C_{15:0}$ anteiso (44%) and $C_{15:0}$ iso (37%). The peptidoglycan type is A3α Lys–Thr–Ala3. MK-9(H_2) (41%), MK-10(H_2) (28%), and MK-11(H_2) (11%) are the predominant menaquinones, while MK-12(H_2), MK-9, MK-10, and MK-11 occur in only small amounts. The cell-wall sugars are galactose and rhamnose. Polar lipids of the type strain are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and one unknown phospholipid.

Sequence accession no. (16S rRNA gene; another strain): AJ639828.

60. **Arthrobacter tumbae** Heyrman, Verbeeren, Schumann, Swings and De Vos 2005, 1463[VP]

tum′ba.e. L. gen. n. *tumbae* of a tomb.

Cells are Gram-stain-positive, short rods and cocci (diameter, 0.8–1 μm) occurring singly, in pairs, or in clusters. They are nonmotile and do not form endospores. Colonies on NA after 48 h are small (<1 mm), yellow–orange, round with entire margins, of low convexity, opaque, and smooth. Do not grow in an anaerobic chamber on NA. Optimum temperature for growth is 22–30°C. Weak growth at 37°C, and no growth at 52°C. Growth at 4°C after 1 week of incubation. Growth on medium with 10% NaCl, but not with 15% NaCl. Catalase-positive and oxidase-negative. Alkaliphilic; pH range for growth of 7–10 with an optimum of 8–9. Using the API CORYNE system, positive reactions are observed for pyrazinamidase, β-glucuronidase, β-galactosidase, and α-glucosidase. Most strains, including the type strain, test positive for gelatinase. Negative reactions are obtained for *N*-acetyl-β-glucosaminidase and fermentation of ribose, xylose, mannitol, and glycogen. Variable

reactions are obtained for nitrate reduction, pyrrolidonyl arylamidase, alkaline phosphatase, esculin (β-glucosidase), urease, and fermentation of glucose, maltose, lactose, and sucrose. Using the API ZYM system, activity is detected for esterase C4, leucine arylamidase, and phosphoamidase (weak). Most strains, including the type strain, test positive for esterase lipase C8 and negative for alkaline phosphatase, valine arylamidase, α-galactosidase, and β-galactosidase. No activity is detected for lipase C14, cystine arylamidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, or α-fucosidase. Variable reactions are obtained for trypsin, chymotrypsin, acid phosphatase, α-glucosidase, and α-mannosidase. Predominant fatty acids are $C_{15:0}$ anteiso (57%) and $C_{15:0}$ iso (17%). The peptidoglycan type is A3α Lys–Thr–Ala_3. MK-9(H_2) (54%) and MK-10(H_2) (25%) are the predominant menaquinones, while MK-7(H_2), MK-8(H_2), and MK-11(H_2) occur in only small amounts. The cell-wall sugar is galactose. Polar lipids of the type strain are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and one unknown phospholipid.

DNA G+C content (mol%): 64.7 (HPLC).

Type strain: DSM 16406, JCM 21773, LMG 19501.

Sequence accession no. (16S rRNA gene): AJ315069.

61. **Arthrobacter uratoxydans** Stackebrandt, Fowler, Fiedler and Seiler 1984, 270[VP] (Effective publication: Stackebrandt, Fowler, Fiedler and Seiler 1983b, 483.)

u.ra.to′xy.dans. N.L. n. *uratum* salt of uric acid; N.L. part. adj. *oxydans* oxidizing; N.L. part. adj. *uratoxydans* uric acid oxidizing.

In young cultures, straight to slightly curved or ellipsoidal rods with metachromic granules to pleomorphic rods which are club-shaped swellings; angular or palisade rods formed by snapping divisions are observed. Gram-stain-positive; 0.8–1.2 × 1.0–5 μm; nonmotile. No capsules; no endospores. Colonies circular, flat, smooth, entire margins, slightly glistening and opaque, 3–4 mm in diameter; creamy white in young cultures to pale yellow in old cultures. Water soluble, pale yellowish brown pigment produced. In nutrient broth, scanty surface growth; no sediments. In gelatin stab cultures, best growth at top and filiform; liquification stratiform. In litmus milk no reaction; slightly alkaline; no coagulation. Nitrate reduced to nitrite. Voges–Proskauer test negative. Indole production negative; hydrogen sulfide production positive; hydrolysis of starch negative; utilization of sodium citrate (Koser's and Christen's medium) positive; utilization of a great variety of organic nitrogen compounds. Uricase strongly positive; hemolysis negative; nonpathogenic. The type strain is positive for pyrazinamidase but negative for β-galactosidase. It can assimilate *N*-acetylglucosamine but not amygdalin, arbutin, cellobiose, D-arabitol, D-mannose, D-turanose, D-xylose, galactose, glycerol, inositol, L-arabinose, maltose, mannitol, melibiose, salicin, sucrose, trehalose, xylitol, β-gentiobiose, or 5-ketogluconate (only type strain investigated; Osorio et al., 1999). Utilizes 5-amino valerate, glyoxylate, L-leucine, L-xylose, and uric acid. Hydrolysis of xanthine and casein; acid is not produced from sugars; cellulose is not decomposed. Aerobic to slightly facultative anaerobic; optimal temperature and pH for growth, 27–35°C and 7–8; thermal death time 10 min at 52°C. The peptide subunit of the peptidoglycan consists alanine, D-glutamic acid, and lysine. The interpeptide bridge contains alanine and glutamic acid (Lys–Ala–Glu type, variation A4α). Major fatty acids are $C_{15:0}$ anteiso (34%), $C_{15:0}$ iso (27%), $C_{17:0}$ anteiso (14%), $C_{17:0}$ iso (11%) and $C_{16:0}$ iso (7%) (Funke et al., 1996).

Type strain: ATCC 21749, CIP 102367, DSM 20647, NBRC 15515, JCM 11944, LMG 16220, VKM Ac-1979.

Sequence accession no. (16S rRNA gene): X83410.

Sequence accession no. (recA): AF214791.

62. **Arthrobacter ureafaciens** (*ex* Krebs and Eggleston 1939) Clark 1955, 112[AL] (*Corynebacterium ureafaciens* Krebs and Eggleston 1939, 310)

u.re.a.fa′ci.ens. N.L. n. *urea* urea; L. v. *facio* to make, produce; N.L. part. adj. *ureafaciens* urea-producing.

Cells are nonmotile. Colonies on yeast extract-peptone media are pale gray, becoming yellow especially when incubated in diffuse daylight at ~20°C. When supplied with biotin, cells grow in suitable mineral salts medium with an ammonium salt as sole nitrogen source and with glucose as carbon and energy source (Keddie et al., 1986). Starch is not hydrolyzed, nitrate is not reduced, and cells do no grow in 10% NaCl. Nicotine blue is not produced from nicotine. Utilizes L-arginine, L-asparagine, L-arabinose, D-galactose, D-glucose, D-ribose, D-xylose, histidinol, inositol, 4-aminobutyrate, and ρ-hydroxybenzoate but not L-histidine, L-leucine, L-rhamnose, butanediol, or malonate. Assimilate citric acid, formic acid, glutaric acid, propionic acid, and uric acid but not adipic acid, benzoic acid, malonic acid, or pimelic acid. Urea is formed from creatinine and uric acid. The cell-wall peptidoglycan is of the Lys–Ala–Thr–Ala type. The whole-cell-wall sugar is galactose (mannose). The principal isoprenoid quinone is MK-9(H_2). The predominant fatty acid is $C_{15:0}$ anteiso (58%), followed by $C_{17:0}$ anteiso (28%), $C_{16:0}$ iso (6%), and $C_{15:0}$ iso (5%) (Kodama et al., 1992).

Source: soil.

DNA G+C content (mol%): 61.7 (T_m).

Type strain: ATCC 7562, CIP 67.3, DSM 20126, NBRC 12140, JCM 1337, LMG 3812, VKM Ac-1121.

Sequence accession no. (16S rRNA gene): X80744.

Sequence accession no. (recA): AF214782.

63. **Arthrobacter woluwensis** Funke, Hutson, Bernard, Pfyffer, Wauters and Collins 1997a, 242[VP] (Effective publication: Funke, Hutson, Bernard, Pfyffer, Wauters and Collins, 1996, 2362.)

wo.lu.wen′sis. N.L. masc. adj. *woluwensis* of or belonging to Woluwe, a town near Brussels, Belgium, where the type strain was isolated from a patient.

The cells are coryneform bacteria which develop into cocci when the cultures become older (72 h). Jointed rods are observed after 1–2 d of incubation. No spores formed. The cells are nonmotile. The organism is obligately aerobic. The colonies are whitish-grayish, smooth, convex, and larger than 2 mm in diameter after 24 h of incubation at 37°C in 5% CO_2 on SBA. The organism is catalase-positive. Nitrate is not reduced. Urea (72 h) and esculin (24 h) are

hydrolyzed. DNase and gelatinase activities are detected within 24 h. Glycerol, galactose, D-glucose, D-fructose, D-mannose, dulcitol, mannitol, sorbitol, *N*-acetylglucosamine, amygdalin, arbutin, salicin, cellobiose, maltose, lactose, melibiose, sucrose, trehalose, melezitose, D-raffinose, β-gentiobiose, D-turanose, D-arabitol, gluconate, 2-keto-gluconate, and 5-keto-gluconate are utilized. Erythritol, D-arabinose, L-arabinose, ribose, D-xylose, L-xylose, adonitol, β-methyl-xyloside, L-sorbose, rhamnose, inositol, α-methyl-D-mannoside, α-methyl-D-glucoside, inulin, starch, glycogen, xylitol, D-lyxose, D-tagatose, D-fucose, L-fucose, and L-arabitol are not utilized. The following enzyme activities are detected: alkaline and acid phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), leucine arylamidase, cystine arylamidase, trypsin, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase. Chymotrypsin, α-galactosidase, β-glucuronidase, and α-fucosidase are not present. The peptidoglycan type is A4α, L-lysine–D-aspartic acid. Major fatty acids are $C_{15:0}$ anteiso (38%), $C_{15:0}$ iso (22%), $C_{17:0}$ anteiso (15%), $C_{17:0}$ iso (6%), and $C_{16:0}$ iso (11%) (Funke et al., 1996).

Sequence accession no. (16S rRNA gene): X93353.

Misclassified species

1. **Arthrobacter viscosus** Gasdorf, Benedict, Cadmus, Anderson and Jackson 1965, 150[AL]

vis.co′sus. L. masc. adj. *viscosus* viscous, sticky; referring to exopolysaccharide production and viscous colonies.

Arthrobacter viscosus was the name given to two polysaccharide-producing bacterial strains. Both strains are considered to be Gram-stain-negative, motile, aerobic rods (ATCC catalog, 1982). The type strain produces from glucose large quantities of a carbohydrate polymer based on galactose, glucose, and mannuronic acid, and contains *meso*-diaminopimelic acid (*meso*-DAP) as cell-wall diamino acid but neither arabinose nor mycolic acids (Keddie and Cure, 1978). The second strain of the species, ATCC 19583, also contains a directly linked peptidiglycan based on *meso*-DAP and lacks arabinose in the cell wall (Schleifer and Kandler, 1972).

Source: Guatemalan soil.

DNA G+C content (mol%): 59.4 (method of analysis specified in Skyring et al., 1971).

Type strain: ATCC 19584; CIP 82.105; DSM 7307; JCM 11566; LMG 16473; NCIB 9729; NRRL B-1973.

Sequence accession no. (16S rRNA gene): AJ639832.

Genus IV. **Citricoccus** Altenburger, Kämpfer, Schumann, Steiner, Lubitz and Busse 2002, 2099[VP]

Hans-Jürgen Busse and Peter Kämpfer

Ci.tri.coc′cus. L. n. *citrus* lemon, citron or citrus, an African tree; N.L. masc. n. *coccus* a sphere; N.L. masc. n. *Citricoccus* lemon-yellow-pigmented coccus.

Cocci, occurring singly, in short chains or in clusters, about 1 µm in diameter; cells are nonmotile, Gram-stain-positive, non-spore-forming, and aerobic. Oxidase-negative and catalase-positive.

The **peptidoglycan consists of the amino acids alanine, glycine, glutamic acid, and lysine** and an **interpeptide chain Lys–Gly–Glu**, peptidoglycan type variation **A4α**. The predominant **menaquinone is MK-9(H_2)**, and moderate amounts of MK-7(H_2) and MK-8(H_2) are present. **Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, four unknown glycolipids, two unknown phospholipids, and an unknown lipid**. The **major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso**. **Spermidine** is the **predominant polyamine**. This genus is a member of the family *Micrococcaceae*.

DNA G+C content (mol%): 63.8–68.

Type species: **Citricoccus muralis** Altenburger, Kämpfer, Schumann, Steiner, Lubitz and Busse 2002, 2099[VP].

Further descriptive information

With >96% sequence similarity in their 16S rRNA genes, species of the genus *Citricoccus* are closely related to the genus *Micrococcus*, the type genus of the family *Micrococcaceae*. Two species have been described so far: *Citricoccus muralis*, the type species of the genus (Altenburger et al., 2002), and *Citricoccus alkalitolerans* (Li et al., 2005b). These species were isolated from samples of a medieval wall painting in the Church of St. Georgen (Austria) and desert soil in eastern Egypt, respectively. They are phylogenetically closely related, and the sequence similarity of their 16S rRNA genes is 99.6% (Li et al., 2005b). On the basis of their 16S rRNA gene nucleotide sequences in databases, at least four additional strains of the genus may be present in institutional culture collections. These strains are designated *Citricoccus* sp. JM-Le (sequence accession no. AB189330), *Micrococcus* sp. P_wp 0222136 (accession no. AY188937), *Micrococcus* sp. V4.40.20p (accession no. AJ244665), and *Citricoccus* sp. 2216.25.22 (accession no. AB094464) and share >98.5% sequence similarity with *Citricoccus muralis*. They were isolated from a fragment of a stalactite in Jourmon Cave (Gifu Prefecture, Japan), from deep-sea sediment of unknown geographical source, from the Western Mediterranean Sea close to Nice, France (Fritz, 2000), and from subsea floor sediment in the southwestern part of the Sea of Okhotsk (Inagaki et al., 2003). In addition Tiago et al. (2004) found *Citricoccus*-like organisms in nonsaline, alkaline environments.

The two established species are very similar. Their DNA–DNA hybridization is relatively high, 56%. They share major chemotaxonomic characteristics, including the peptidoglycan type A4α (Schleifer and Kandler, 1972), murein type A11.40/56 (DSMZ, 2001), menaquinone MK-9(H_2) as the predominant quinone, a similar polar lipid profile dominated by diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol, anteiso and a similar fatty acid profile comprised almost exclusively of $C_{15.0}$ anteiso and other branched-chain fatty acids. However, significant quantitative differences in the abundance of certain fatty acids

and several physiological traits as well as results from DNA–DNA hybridization confirm their status as separate species (Table 97).

No species of this genus has been reported to be pathogenic.

Enrichment and isolation procedures

No specific isolation medium has been described. Good growth occurs on PYES agar (Altenburger et al., 2002), R2A agar and TS agar (Oxoid), and a very low-nutrient medium, CasMM agar (Altenburger et al., 1996), at 10–28°C. Moderate growth occurs at 4 and 37°C, but no growth is observed at 40°C.

Maintenance procedures

Citricoccus cultures may be lyophilized by common procedures used for many bacteria or stored in 21% glycerol at −80°C.

Differentiation of the genus *Citricoccus* from other genera

Citricoccus may be distinguished from other genera in the family *Micrococcaceae* by their cell-wall peptidoglycan, menaquinone type, colony pigmentation, and G+C content.

TABLE 97. Characteristics distinguishing the two species of the genus *Citricoccus*, *Citricoccus muralis* and *Citricoccus alkalitolerans*[a,b]

Characteristic	*C. muralis*	*C. alkalitolerans*
Growth in the presence of methyl red	+	−
Presence of:

List of species of the genus *Citricoccus*

1. **Citricoccus muralis** Altenburger, Kämpfer, Schumann, Steiner, Lubitz and Busse 2002, 2099[VP]

mu.ra′lis. L. masc. adj. *muralis* pertaining or belonging to walls.

Morphological, chemotaxonomic and general characteristics are as described for the genus. Colonies reach a maximum size of 3 mm after 2 weeks of incubation. They are yellow pigmented, circular, convex, and opaque. Growth is good at room temperature and 28°C, moderate at 4°C, absent at 37°C, good at NaCl concentrations of up to 7% (w/v), weak at 10% (w/v), and absent at 15% (w/v) and present at initial pH values between 6 and 10. No acid is produced from glucose, sucrose, salicin, inositol, rhamnose, trehalose, cellobiose, and D-mannose. Gluconate, D-glucose, D-maltose, D-mannose, D-sucrose, D-trehalose, acetate, propionate, *cis*-aconitate, fumarate, glutarate, DL-3-hydroxybutyrate, DL-lactate, L-malate, oxoglutarate, pyruvate, L-aspartate, L-leucine, L-phenylalanine, L-proline, L-serine, 3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate but not *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, α-D-melibiose, L-rhamnose, D-ribose, salicin, D-xylose, adonitol, iso-inositol, maltitol, D-mannitol, D-sorbitol, putrescine, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, itaconate, mesaconate, suberate, L-alanine, β-alanine, L-histidine, L-ornithine, and L-tryptophan serve as sole carbon sources for growth. Esculin, pNP-β-D-glucopyranoside, 2-deoxythymidine-5′-pNP-phosphate, L-alanine-pNA and L-proline-pNA but not pNP-β-D-galactopyranoside, pNP-β-D-glucuronide, pNP-α-D-glucopyranoside, pNP-β-D-xylopyranoside, bis-pNP-phosphate, pNP-phenyl-phosphonate, pNP-phosphoryl-choline, and L-glutamate-γ-3-carboxy-pNA are hydrolyzed. Tween 20 and Tween 80 but not casein and starch are decomposed. Nitrate is not reduced to nitrite. H_2S and indole are not produced. Urease is positive. The peptidoglycan contains of Ala, Gly, Glu, and Lys in a molar ratio of 1.3:0.8:2.0:1.0, and the interpeptide bridge consists of Lys–Gly–Glu (peptidoglycan type A4α, murein type A11.40/56). The type strain contains the menaquinones (molar ratio in parentheses) MK-9(H_2) (64%), MK-7(H_2) (24%), and MK-8(H_2) (14%). The abundant fatty acids are $C_{15:0}$ anteiso (55.6%), $C_{17:0}$ anteiso (27.0%), $C_{16:0}$ iso (8.0), $C_{15:0}$ iso (6.4%), $C_{13:0}$ anteiso (1.2%), $C_{17:0}$ iso (1.1%), and $C_{16:0}$ (0.8%). The polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, four unknown glycolipids, two unknown phospholipids, and a remaining unidentified lipid. Spermidine is the predominant polyamine.

DNA G+C content (mol%): 68 (HPLC).

Type strain: 4-0, DSM 14442, CCM 4981, CCUG 51768, JCM 12134.

Sequence accession no. (16S rRNA gene): AJ344143.

2. **Citricoccus alkalitolerans** Li, Chen, Zhang, Kim, Park, Lee, Xu and Jang 2005b, 88[VP]

al.ka.li.to′le.rans. N.L. n. *alkali* (from the Arabic articel *al* the; Arabic n. *qaliy* the ashes of saltwort), alkali; L. part. adj. *tolerans* tolerating; N.L. part. adj. *alkalitolerans* referring to the ability of the organism to tolerate alkaline media.

Cells are aerobic, Gram-stain-positive, nonmotile, non-spore-forming cocci, with diameters of 0.5–0.8 µm. Colonies on PYES* medium are light yellow, circular, entire, somewhat convex, opaque, and approximately 1.5 mm in diameter after 24 h of growth at 28°C. Growth occurs between 10 and

*PYES medium: 3 g/l peptone from casein, 3 g/l yeast extract, 2.3 g/l di-sodium succinate, pH 7.2.

37°C and optimally at 28°C. No growth is observed at 4 or 40°C. The optimum growth pH and NaCl (w/v) concentration ranges are 8.0–9.0 and 0–5%, respectively. Catalase-positive and oxidase-negative. Urease- and tyrosinase-negative. Tweens 20 and 80, casein, and starch are not hydrolyzed. H_2S and indole are not produced. Nitrate is not reduced to nitrite. Lipase and α-glucosidase tests are positive. Tests for ornithine and lysine decarboxylase, arginine dihydrolase, β-glucuronidase, α- and β-galactosidase, *N*-acetyl-β-glucosaminidase, and β-glucosidase are negative. Glucose, galactose, sucrose, arabinose, mannose, mannitol, maltose, starch, xylose, ribose, cellobiose, salicin, sorbitol, lactose, dextrin, amygdalin, glycine, and lysine but not fructose, *N*-acetyl-α-glucosamine, L-alanine, β-alanine, L-histidine, L-ornithine, L-tryptophan, and arginine serve as sole carbon sources. The peptidoglycan is of the Lys–Gly–Glu type (A4α). The major quinone is menaquinone MK-9(H_2). The polar lipid profile contains diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and two unknown glycolipids. The abundant cellular fatty acids are: $C_{15:0}$ anteiso (75%), $C_{15:0}$ iso (13%), $C_{17:0}$ anteiso (4%), $C_{16:0}$ iso (2%), $C_{15:0}$ (2%), $C_{14:0}$ iso (1%), $C_{13:0}$ iso, $C_{17:0}$ iso, and $C_{13:0}$ anteiso. The amounts of $C_{13:0}$, $C_{14:0}$, and $C_{16:0}$ are less than 1%.

Genus V. **Kocuria** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 690[VP]

ERKO STACKEBRANDT AND PETER SCHUMANN

Ko.cu′ri.a. N.L. fem. n. Kocuria, named after Miroslav Kocur, a Slovakian microbiologist for his pioneering studies on Gram-stain-positive cocci.

Cells coccoid. Gram-stain-positive. Nonencapsulated. Endospores not formed. Nonmotile. Chemo-organotrophic; metabolism is strictly respiratory. **Aerobic;** strains of one species are slightly facultatively anaerobic. Catalase-positive. Nonhalophilic. Mesophilic. **The peptidoglycan type is A3α (L-Lys–L-Ala$_{3-4}$).** Mycolic acids and teichoic acids are absent. **Menaquinones are hydrogenated; the predominant menaquinones are MK-7(H_2), MK-8, or MK-9(H_2)**, either alone or in combination. Polar lipids include diphosphatidylglycerol and phosphatidylglycerol; phosphatidylinositol is present in one species. **The major fatty acid is $C_{15:0}$ anteiso**.

DNA G+C content (mol%): 66–75.

Type species: **Kocuria rosea** (Flügge 1886) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 690 (*Micrococcus roseus* Flügge 1886 183[AL]).

Further descriptive information

Following a thorough phylogenetic and chemotaxonomic study, the genus *Micrococcus* was dissected (Stackebrandt et al., 1995) leading to the description of *Dermacoccus*, *Kocuria*, *Kytococcus*, and *Nesterenkonia*. The latter three genera are members of the family *Micrococcaceae*, order *Micrococcales*, within the emended order *Actinomycetales* (Buchanan 1917) Stackebrandt et al. 1997. Within this family genera are found which are defined by either spherical cells or cells which undergo a rod–coccus life cycle. The exception is *Renibacterium*, characterized by short rods. This study demonstrated the phylogenetic relevance of chemotaxonomic markers, in that novel combinations of cell-wall structure and profiles of menaquinones, fatty acids, and polar lipids were indicative of a new phylogenetic lineage at the genus rank. The new genus *Kocuria* embraced three former *Micrococcus* species, i.e. *Kocuria rosea* (*Micrococcus roseus* Flügge 1886), *Kocuria varians* (*Micrococcus varians* Migula 1900), and *Kocuria kristinae* (*Micrococcus kristinae* Kloos et al. 1974). Based upon 16S rRNA gene sequence similarities, *Kocuria* species appear to be equidistantly related to members of *Arthrobacter* and *Rothia* but the bootstrap values of the deeply branching lineages within this family are low, thus without statistical significance (Figure 136).

Kocuria species resemble each other in the majority of chemotaxonomic properties and differ from each other mostly in quantitative composition of these markers. The peptidoglycan is characterized by the presence of lysine in position 3 of the peptide subunit. The interpeptide bridge consists of 3 or 4 L-alanine residues, thus defined as the A3α variation (Schleifer and Kandler, 1972). The isoprenoid quinones are hydrogenated menaquinones MK-8(H_2), MK-9(H_2), and MK-7(H_2), occurring either as a single component or in combination with each other. The major fatty acid is $C_{15:0}$ anteiso (>50% of total) but $C_{15:0}$ iso and $C_{16:1}$ represent about 10% each of the total. The base composition of DNA spans a rather broad range (60–75 mol%), which may be due to the different methods used for quantitation. At the interspecies level, a range of 9% and 6% has been determined for *Kocuria rosea* and *Kocuria varians*, respectively, species for which more than the type strain is available for investigation. The extreme values were determined for the recently described type strains of *Kocuria marina* (60 mol%) and *Kocuria himachalensis* (75.3 mol%).

A comparative study on physiological properties which includes all type strains of *Kocuria* is lacking. Therefore only fragmentary information exists on optimal temperature, pH, salt tolerance, and the like for growth. Most *Kocuria* strains grow between 20 and 37°C; *Kocuria aegyptia* can grow at up to 40°C, *Kocuria marina* even up to 43°C. Only the type strains

of *Kocuria polaris* and *Kocuria marina* are able to grow at 5°C. Strains of *Kocuria polaris* and *Kocuria palustris* fail to grow at 37°C. Salt tolerance is variable; if indicated, most strains tolerate 5% NaCl but only one strain tolerates 15% NaCl. The pH range of growth may be broad (5–12 for *Kocuria aegyptia* and 7–12 for *Kocuria polaris*) or narrow, usually slightly alkaliphilic. All species can produce acids from one or more carbohydrates which distinguish them from authentic members of *Micrococcus*. The decrease in medium pH due to acid formation from fermented glucose has only been determined for *Kocuria varians* (pH 4.3–5.9). The degrading capacity differs significantly among species. Most strains do not degrade DNA and starch. Gelatin can be hydrolyzed by some species, though the ability to hydrolyze starch and gelatin is variable in those two species for which more than the type strains have been investigated. Esterase and lipase reactions differ among species; in most cases Tween 80 cannot be utilized. No information is available on metabolic pathways for carbohydrate dissimilation.

DNA–DNA hybridization studies were conducted between several pairs of type strains (Kim et al., 2004; Kotoučková et al., 2004; Kovács et al., 1999; Li et al., 2006; Mayilraj et al., 2006; Rainey et al., 1997; Reddy et al., 2003; Tang and Gillevet, 2003) most of which share lower than 98.8% 16S rRNA similarities. In each case, the corresponding DNA–DNA reassociation values were lower than 60%. Even at a 16 rRNA gene sequence similarity of 99.8% (*Kocuria polaris* versus *Kocuria rosea*), the corresponding DNA reassociation value was as low as 71%. The highest matching values were found for the type strains of *Kocuria erythromyxa* and *Kocuria rosea* (99.9% sequence rRNA gene similarity at 95% DNA similarity) which has led to the union of these species (Rainey et al., 1997). These data clearly indicate a threshold level of 98.8% 16S rRNA gene sequence similarity is essential for membership in *Kocuria*.

Type strains of species originate from a wide range of habitats, including meat (*Kocuria carniphila*, *Kocuria varians*, and *Kocuria kristinae*; Frank et al., 2003), milk (*Kocuria* spp.), mammalian skin (*Kocuria kristinae*, *Kocuria varians*), marine sediment (*Kocuria marina*) and fresh water (*Kocuria rosea*, *Kocuria varians*), cold (*Kocuria himachalensis*), temperate (*Kocuria rosea*) and desert (*Kocuria aegyptia*) soils, cyanobacterial mat (*Kocuria polaris*), and the phyllosphere (*Kocuria palustris*). Many strains, which are affiliated to genus and species, are characterized exclusively on the basis of partial and almost complete 16S rRNA gene sequences. Only these have been deposited in public databases without publication of additional phenotypic circumscriptions. From the information accompanying sequence accession numbers, the origin of isolates support the widespread occurrence of *Kocuria* strains: soil (DQ059671), rhizosphere and phyllosphere (e.g. AF542072, AY838796), aerosolized dust (e.g. AY211105, AY211167, AY278921, AY741253), marine waters (e.g. AY241412, AY269864, AY332098, and AY731367), Mariana Trench deep sediment (Pathom-Aree et al., (2006a) [AY894331]), indoor facilities (e.g. AY030315, AY775563), and cold habitats such as glaciers and the Antarctic environment (AY526638, AY864652, and AY987383). The shielding effect of pigment against UV and the coccoid morphology may contribute to the survival of *Kocuria* strains in dust clouds thousands of kilometers away from their origin (i.e. Saharan dust collected on the US Virgin Islands).

Little information on the occurrence of uncultured *Kocuria* strains has emerged from the analysis of 16S rDNA clone libraries. One clone (AF385532) was found as a new phylotype in lesions of noma cancrum oris, which is a severe gangrenous disease of the oral cavity (Paster et al., 2002). Other single clones were found by Bowman and Nowak (2004) as part of the salmonid gill microbial population, and by McGarvey et al. (2004) in dairy wastewater.

Pathogenicity. Members of the genus *Kocuria* belong to the commensal microbes on human skin, mucous membranes, in the oral cavity and outer ear canal (Frank et al., 2003; Szczerba, 2003b; Szczerba and Krzeminski, 2002) and were detected in indoor environments and in bacterial contaminations of airplanes (Gorny and Dutkiewicz, 2002; McManus and Kelley, 2005). Although caution should be exercised in the differentiation between true infection and contamination, the fact remains that the number of reports implicating members of the family *Micrococcaceae* in clinical cases mainly occurring in immunocompromised patients has increased in recent years (Goodfellow, 1998; Szczerba, 2005). *Kocuria rosea* and *Kocuria kristinae*, e.g. were reported to cause catheter-related bacteremia in patients with severe underlying diseases (Altuntas et al., 2004; Basaglia et al., 2002). An infection by *Kocuria kristinae* associated with acute cholecystitis was diagnosed and successfully treated with levofloxacin (Ma et al., 2005). The following antibiotics are recommended for the treatment of infections caused by *Kocuria* strains or by other representatives of the family *Micrococcaceae*: Amoxicillin with clavulanic acid, doxycycline, cetriaxone, cefuroxime, or amikacin (Szczerba, 2003a). Opportunistic infections are usually serious and difficult to diagnose by routine tests in clinical laboratories. Since the unambiguous identification of strains of the genus *Kocuria* requires a polyphasic strategy, reports on *Kocuria* infections diagnosed using commercial diagnostic test systems are difficult to evaluate. When using only phenotype-based identification systems, phenotypically variable staphylococci may be misidentified as *Kocuria varians* as demonstrated by a polyphasic study (Ben-Ami et al., 2003). Recent molecular sequencing and typing studies aimed at the phylogenetic diversity of environmental samples resulted in the detection of *Kocuria* spp. A combination of 16S rRNA gene amplification and subsequent single strand conformation polymorphisms (SSCP) of the variable region V3 was used to determine the change in microbial populations in goat milk (Callon et al., 2007). *Kocuria* spp. were detected among other bacteria commonly encountered in milk. A combination of community-level physiological profiling and rRNA restriction analysis (ARDRA) on bacterial communities of reed periphyton have also led to the detection of *Kocuria* spp. among the most frequently isolated strains (Borsodi et al., 2007).

Enrichment and isolation procedures

For the isolation of strains from mammalian skin, the procedures of Kloos and Musselwhite (1975) and of Kloos et al. (1976) using P agar (Naylor and Burgi, 1956) are recommended. Although there are no selective procedures to isolate

such strains, spreading colonies of fungi or bacilli may be inhibited by addition of cycloheximide (50 μg/ml; Kloos et al., 1976) or supplementing the isolation media with 7% NaCl (Schleifer et al., 1981), respectively. Repression of staphylococci on skin can be achieved by using furazolidone agar (FTO agar; von Rheinbaben and Hadlock, 1981). Strains of *Kocuria varians* and *Kocuria kristinae* have also been isolated on *Corynebacterium* agar consisting of tryptically digested casein peptone (10.0 g), yeast extract (5.0 g), glucose (5.0 g), NaCl (5.0 g), and agar (15.0 g) per 1000 ml of distilled water (pH 7.2–7.4). *Kocuria* strains may be isolated from soil or sand by the procedure described by Prauser et al. (1997) in which a diluted soil suspension in phosphate buffer is mixed with solubilized organic agar medium with agar content reduced to 0.6% (w/v) at 48°C. This mixture is subsequently poured on organic agar medium containing 1.5% (w/v) agar in Petri dishes and incubated at 28°C for 4–6 d until appearance of colonies. *Kocuria polaris* was isolated from Antarctic Bacterial Medium (ABM) plates containing 0.5% (w/v) peptone, 0.2% (w/v) yeast extract, and 1.5% (w/v) agar (pH 6.9) and incubated at 5°C (Reddy et al., 2003). *Kocuria himachalensis* was obtained on Tryptone Soy Broth (Oxoid CM 129). *Kocuria marina* was isolated on Bacto Marine Broth (Difco 2216). *Kocuria aegyptia* was recovered on a medium containing (g l<MIN>1): glucose, 10.0; peptone, 5.0; yeast extract, 5.0; KH_2PO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; Na_2CO_3, 10.0, and agar, 15; pH, 10–10.5. Sodium carbonate was sterilized separately and then added to the medium. $NaHCO_3$-Na_2CO_3 buffer was used to adjust the pH (Li et al., 2006).

Cells for taxonomic studies can be cultivated on trypticase soy yeast extract medium consisting of trypticase soy broth (30.0 g), yeast extract (3.0 g), and agar (15.0 g) per 1000 ml of distilled water (pH 7.0–7.2). *Kocuria kristinae* should be cultivated at 37°C, whereas all other representatives of the genus grew optimally at 28–30°C.

Maintenance procedures

Strains have been stored for some weeks as slant cultures at 4°C and as 20% (w/v) glycerol suspensions at −20°C and at −80°C. Long-term preservation methods include freeze drying in skim milk and in liquid nitrogen at −196°C.

Differentiation of the genus *Kocuria* from other genera

Table 98 indicates the characteristics useful to distinguish *Kocuria* from other members of the family *Micrococcaceae*. The isolated phylogenetic position is supported by chemotaxonomic characters which differentiates *Kocuria* from other coccid members of the family. However, this is not achieved by a single feature but by a combination of four chemotaxonomic properties. Cell wall type and variation A3α are also found in members of the phylogenetically neighboring genera *Renibacterium*, *Rothia*, and in *Arthrobacter* group I (*Arthrobacter globiformis* and relatives). Hydrogenated menaquinones of the types MK-8(H_2), MK-9(H_2), and/or MK-7(H_2) are also found in *Arthrobacter* group I, *Citricoccus*, and *Micrococcus*. The range of G+C mol% of DNA for *Kocuria* and members of many other genera in the family is similar, but for *Yania*, *Rothia*, and *Renibacterium* the range is distinctly below 60%. The polar lipids are similar though slight differences exist among the genera. Likewise, the composition of major components of fatty acids do not allow discrimination between genera; qualitative and quantitative assessment of the full range of fatty acid profiles, however, will allow assignment of strains to species.

Taxonomic comments

The species *Kocuria erythromyxa* was proposed by Rainey et al. (1997) as a result of a phylogenetic study on members of *Deinococcus* and *Deinobacter*. The species *Deinococcus erythromyxa* showed 99.9%, 96.6%, and 95.7% 16S rDNA gene sequence similarity to *Kocuria roseus*, *Kocuria varians*, and *Kocuria kristinae* respectively, thus confirming previous chemotaxonomic evidence that *Deinococcus erythromyxa* was more closely related to members of the genera *Arthrobacter* and *Micrococcus* than to *Deinococcus* (Embley et al., 1987). A DNA–DNA reassociation value of 21%, determined for the pair *Deinococcus erythromyxa* (then designated *Sarcina erythromyxa*) and *Kocuria rosea* (then designated *Micrococcus roseus*) (Brooks et al., 1981) was used as evidence to reclassify *Deinococcus erythromyxa* as *Kocuria erythromyxa*. Subsequent pairwise comparison of phenotypic, chemotaxonomic, and genomic properties of the type strains of *Kocuria rosea* and *Kocuria erythromyxa* indicated that these taxa were in fact members of the same species. Above all, this conclusion was based on a DNA–DNA reassociation value of 95%, identical fatty acid patterns, and almost identical physiological reactions against substrates provided by the BIOLOG plate. According to Rule 42 of the International Code of Nomenclature of Bacteria which requires that the oldest legitimate epithet be retained when taxa of equal rank are united, *Kocuria* (*Micrococcus*) *rosea* (Flügge 1886) had priority over *Kocuria* (*Deinococcus*) *erythromyxa* (Brooks and Murray, 1981).

Notably, the name *Kocuria erythromyxa* was proposed for an organism that had a long history of changing genera affiliations. The organism was described as "*Micrococcus erythromyxa*" by Zopf (1891) and as "*Sarcina erythromyxa*" by Chester (1901). Other combinations were "*Bacterium erythromyxa*" (Migula, 1900), "*Bacillus erythromyxa*" (Matzuschita, 1902), and "*Mycobacterium erythromyxa*" (Krasil'nikov, 1941). The species which was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980) received formal status when *Micrococcus roseus* UWO 1045 was described as the type strain of *Deinococcus erythromyxa* (Brooks and Murray, 1981), though as a species *incertae sedis*.

Based upon phylogenetic and chemotaxonomic analyses and supported by a DNA–DNA reassociation value of 87.1% and a G+C content of 72 mol%, it was concluded that *Pelczaria aurantia* ATCC 49321^T (= DSM 12801^T) and *Kocuria rosea* DSM 20447^T are members of the same taxon (Schumann et al., 2000). According to Rule 42 of the Bacteriological Code (Lapage et al., 1992) and on the basis of priority, the two species must be united in the genus *Pelczaria* (Poston, 1994) and in the same species as both species are the type species of the respective genera. As the type strain of *Pelczaria aurantia* did not conform on re-investigation (Schumann et al., 2000) to the description of the type strain of *Pelczaria aurantia* as described by Poston (1993), the Judicial Commission (2005) considered a request of Tindall et al. (2000) to designate the organisms currently deposited as ATCC 49321 and DSM 12801 (i) as members of the species *Kocuria rosea* and (ii) not the species *Pelczaria aurantia*. The genus name

[l]Glycine or glycine amide bound to α-carboxyl group of glutamic acid at position 2 of peptide subunit.

[m]D-Alanine amide bound to α-carboxyl group of glutamic acid at position 2 of peptide subunit.

[n]One, or combinations of more components.

Pelczaria and the species name *Pelczaria aurantia* are placed on the list of *nomina rejicienda*.

Strain ATCC 9341, named "*Sarcina lutea*" by the US Food and Drug Administration, was affiliated to *Micrococcus luteus* by Baird-Parker (1974). Comparison of characteristics between strain ATCC 9341 and the type strain of *Micrococcus luteus* ATCC 4698^T revealed obvious phenotypic differences (Tang and Gillevet, 2003). As strain ATCC 9341 has been used as a quality-control strain in a number of applications, as a standard culture in several official methods, manuals, and the Code of Federal Regulations (for references, see Tang and Gillevet, 2003) it appeared necessary to reinvestigate its taxonomic position. 16S rRNA gene sequence analysis found 99% similarity between strain ATCC 9341 and the type strain of *Kocuria rhizophila* DSM 11926^T (accession no. Y16264). Because of identity in peptidoglycan structure and fatty acid composition, strain ATCC 9341 was affiliated to the species *Kocuria rhizophila*, although DNA–DNA reassociation between ATCC 9341 and the type strain *Kocuria rhizophila* BAA-50^T was 67.6% only and the Riboprint pattern of strain ATCC 9341 did not match that of *Kocuria rhizophila* ATCC BAA-50^T.

Acknowledgements

We thank Rüdiger Pukall and Jennifer Gregor for providing physiological and chemotaxonomic data, respectively, and Jola Swiderski for phylogenetic analyses.

Differentiation of species of the genus Kocuria

Species of the genus *Kocuria* are moderately to closely related among themselves, forming four intrageneric lineages. 16S rRNA gene sequence similarities indicate the presence of two strain clusters and two individual lineages. The branching order is supported by bootstrap values of higher than 70%. A few inconsistencies in some of the original sequences deposited in public databases were corrected and the new accession numbers are indicated in the footnote to Figure 138. Members of the two clusters share higher than 98% similarities among each other, while the four lineages are separated from each other by similarities of 95.5–97.5%. The clustering of strains within each of the two clusters is neither correlated with similarities at the phenotypic level nor with the habitats from which they were isolated (Table 99).

Riboprint analysis by the RiboPrint robot (Qualicon, Dupont) indicates that a unique pattern defines each type strain (Figure 139). As the number of bands is low, the phylogenetic significance is restricted and the resulting dendrogram of ribopatterns bears no similarity with the 16S rRNA gene dendrogram. At the intraspecies level, the patterns may vary significantly and the ribopattern of the type strain does not necessarily characterize additional strains of the species.

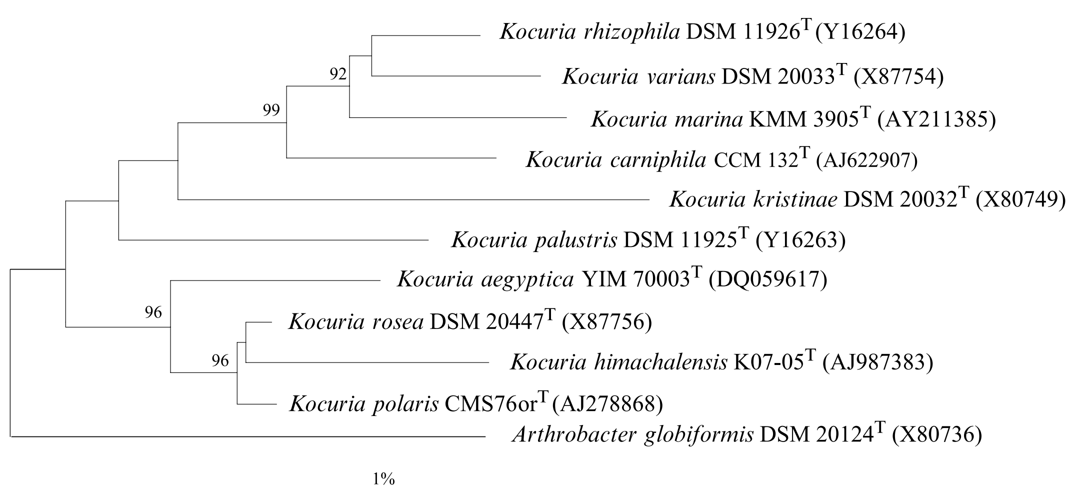

FIGURE 138. Neighbor joining tree (Felsenstein, 1993b) based on 16S rRNA gene sequences of members of the genus *Kocuria*, represented by their type strains. Bootstrap values (>90%) of 500 resamplings (Felsenstein, 1985) are indicated at nodes. The scale represents 1 inferred nucleotide change per 100 nucleotides.

List of species of the genus *Kocuria*

1. **Kocuria rosea** (Flügge 1886) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 690 (*Micrococcus roseus* Flügge 1886 183[AL])

ro′se.a. L. fem. adj. *rosea* rose colored, rosy.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Cells are spherical (diameter, 1–1.5 µm) and occur in pairs, tetrads, and clusters. Colonies are circular, slightly convex, smooth (occasionally rough), and pink or red. No water-soluble exopigment is formed. Colony morphology and color become more distinct with age; cell morphology is not culture-, age-, or medium-dependent. Growth is stimulated by cysteine and thiamine or cysteine, thiamine, and pantothenic acid. Growth in nutrient broth is followed by moderate turbidity and a deposit; in some strains a surface ring and pellicle are formed. Grows well in the presence of NaCl concentrations up to 7.5% NaCl. Oxidase test negative (rarely weakly positive); benzidine test positive. Nitrate reduction positive or weakly positive; nitrite reduction negative. Arginine dihydrolase, phenylalanine deaminase, urease, lecithinase, phosphatase, β-galactosidase, and bound human and rabbit coagulase negative. Most strains do not grow on inorganic nitrogen agar and on Simmons' citrate agar. Hydrolysis of esculin and gelatin is negative; hydrolysis of Tween 80 and starch is variable. Production of acetoin is negative or weak; indole and hydrogen sulfide are not produced. Most strains utilize rhamnose, xylose, and glucitol. No acid is formed from mannose, galactose, lactose, and glycerol; acid production from glucose is variable. The optimal growth temperature is in the range 25–37°C. All strains are susceptible to tetracycline, erythromycin, oleandomycin, novobiocin, methicillin, kanamycin, polymyxin, vancomycin, penicillin G, streptomycin, chloramphenicol, and neomycin. Slightly resistant or resistant to lysozyme. Saprophytic. Nonhemolytic. The cytochromes are cytochromes aa_3, c_{550}, c_{557}, b_{564}, and d_{626}.

Source: water and soil.

DNA G+C content (mol%): 66–75 (T_m).

Type strain: ATCC 186, DSM 20447, CCM 679, CCUG 4312, CIP 71.15, IEGM 394, NBRC 3768, JCM 11614, LMG 14224, NCTC 7523, NRRL B-2977, VKM B-1823.

Sequence accession no. (16S rRNA gene): X87756.

2. **Kocuria aegyptia** Li, Zhang, Schumann, Chen, Hozzein, Tian, Xu and Jian 2006, 735[VP]

a.e.gyp′ti.a. L. fem. adj. aegyptia from Egypt, referring to the country of isolation.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Cells are Gram-positive, coccoid, occurring in pairs, tetrads or clusters, and non-motile, and non-endospore-forming. Colonies are pink, circular, opaque, and approximately 2 mm in diameter. The strain cannot grow in ISP 2 medium without salt, but can grow in ISP 2 medium containing 1–5% NaCl, 1–10% KCl, 1–5% $MgCl_2 \cdot 6H_2O$, or 1–5% $CaCl_2$, respectively, with optimum growth occurring at 3%, except for KCl at 5%. Temperature range for growth is 20–40°C, with optimum growth occurring at 28°C. pH range for growth is 5.0–12.0, with optimum growth occurring between 10.0 and 10.5. Oxidase test with

tetramethyl-*p*-phenylenediamine is negative. The strain is negative for urease, *N*-acetyl-glucosaminidase, L-aspartic arylamidase, β-galactosidase, α-galactosidase, α-maltosidase, β-glucuronidase, Tween 20 and Tween 80 esterase, tyrosinase, Methyl red and Voges–Proskauer tests, melanin, indole, and H_2S production, nitrate reduction, gelatin liquefaction, milk peptonization and coagulation, and starch hydrolysis, but positive for catalase-reaction and ornithine decarboxylase, arginine dihydrolase, lysine decarboxylase, lipase, β-glucosidase, and ammonia. Maltose, D-glucose, D-cellobiose, D-trehalose, D-sorbitol, D-fructose, D-mannose, and dextrin can be utilized as the only carbon source. Acid is produced from D-fructose but not from mannose, trehalose, raffinose, ribose, and cellobiose.

Source: A saline alkaline desert soil sample collected from Egypt.

DNA G+C content (mol%): 73 (T_m).

Type strain: CCTCC AA203006, CIP 107966, JCM 14735, YIM 70003, KCTC 19010, DSM 17006.

Sequence accession no. (16S rRNA gene): DQ059617.

3. **Kocuria carniphila** Tvrzová, Schumann, Sedláček, Páčová, Spröer, Verbarg and Kroppenstedt 2005a, 140[VP]

car.ni′phi.la. L. n. *caro* gen. *carnis* meat; N.L. fem. adj. *phila* (from Gr. fem. adj. *philê*) loving; N.L. fem. adj. *carniphila* meat-loving.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Cells are coccoid, 1–1.5 μm in diameter, occurring in pairs and tetrads, Gram-positive, non-motile, non-acid-fast, and non-spore-forming. Colonies are yellow, circular, convex, and opaque. Obligately aerobic. Good growth at 28–37°C. Growth over pH range 7.0–9.1. Very weak growth in the presence of 10% (w/v) NaCl. Catalase-, β-galactosidase- and β-glucuronidase-positive. Negative for oxidase, Voges–Proskauer test, arginine dihydrolase, ornithine decarboxylase, urease, phosphatase, and pyrrolidonyl arylamidase. Nitrate is reduced to nitrite. Nitrite is not reduced. Starch, gelatin, Tween 80, and esculin are not hydrolyzed. Acidification of glucose, fructose, and lactose is positive. Weak acid production from maltose and sucrose. Acid production is negative from mannose, raffinose, trehalose, mannitol, xylitol, melibiose, xylose, turanose, ribose, cellobiose, methyl α-D-glucopyranoside, *N*-acetylglucosamine, and arabinose. The following compounds are utilized: dextrin, Tween 40, Tween 80, *N*-acetyl-D-glucosamine, *N*-acetyl-D-mannosamine, amygdalin, D-fructose, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, D-gluconic acid, α-D-glucose, *myo*-inositol, maltotriose, D-mannitol, D-mannose, D-melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl glucose, D-psicose, D-ribose, sucrose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, β-ketovaleric acid, L-lactic acid, mono-methyl succinate, propionic acid, pyruvic acid, succinic acid, *N*-acetyl-glutamic acid, L-glutamic acid, L-pyroglutamic acid, glycerol, thymidine 5′-monophosphate and glucose 6-phosphate. α-Cyclodextrin, β-cyclodextrin, D-arabitol, arbutin, D-galactose, lactulose, D-melezitose, methyl α-D-glucoside, methyl β-D-glucoside, methyl α-D-mannoside, palatinose, D-raffinose, salicin, sedoheptulosan, D-tagatose, xylitol, lactamide, D-lactic acid methyl ester, D-malic acid, L-malic acid, alaninamide, D-alanine, L-alanine, L-alanyl glycine, glycyl-L-glutamic acid, putrescine, inosine, uridine, adenosine 5′-monophosphate, and uridine 5′-monophosphate cannot be utilized.

Source: meat.

DNA G+C content (mol%): 71 (HPLC).

Type strain: CCM 132, DSM 16004, JCM 14118.

Sequence accession no. (16S rRNA gene): AJ622907.

4. **Kocuria himachalensis** Mayilraj, Kroppenstedt, Suresh, Saini and Chakrabarti 2006, 1974[VP]

hi.ma.cha. len′ sis. N.L. fem. adj. himachalensis of or pertaining to the Indian State of Himachal Pradesh, where the type strain was isolated.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Gram-positive cocci, strictly aerobic. Colonies circular, orange/pink colored, and 2 to 5 mm in diameter on TSA agar. No growth occurs at 5°C and 42°C. Growth occurs at 20–30°C (optimal temperature 28°C) and pH up to 10 (optimal pH 7.5). Catalase and oxidase are negative. Does not grow in the presence of 8% NaCl or higher. It is negative for starch hydrolysis, gelatin hydrolysis, indole, methyl red, Voges-Proskauer, and nitrate reduction. Hydrogen sulfide is not produced. Capable of utilizing D-maltose, D-melibiose, L-arabinose, L-alanine, D-cellobiose, D-mannitol, pyruvate, inulin, D-raffinose, and negative for adonitol, *meso*-inositol, lactose as sole carbon sources. Capable of utilizing L-arginine, L-aspartic acid, L-asparagine, L-glutamic acid, L-leucine, and L-phenylalanine as sole nitrogen sources. Acid is produced aerobically from D-glucose, D-mannose, D-mannitol, L-rhamnose, and D-xylose.

Source: soil, one and a half feet below ice glacier, ASL 4200M, Kibber village of Spiti valley, Himachal Pradesh, India.

DNA G+C content (mol%): 75 (T_m).

Type strain: K07-05, JCM 13326, MTCC 7020, DSM 44905.

Sequence accession no. (16S rRNA gene): AJ987383.

5. **Kocuria kristinae** (Kloos, Tornabene and Schleifer 1974). Stackebrandt, Koch, Gvozdiak and Schumann 1995, 690 *Micrococcus kristinae* Kloos, Tornabene and Schleifer 1974, 87[AL]

kris.ti′na.e. N.L. gen. fem. n. *kristinae* of Kristin; named for Kristin Holding, from whom this organism was originally isolated.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Spheres (diameter, 0.7–1.1 μm) occur in tetrads which may form large adherent clusters. Colonies are circular, entire, or crenate, convex, smooth or rough, up to 2 mm in diameter, and pale cream to pale orange; with time the color in the colony center becomes more intense. Colony morphology and color become more distinct with age; cell morphology is not culture age- or medium-dependent.

Does not produce a water-soluble exopigment. Slightly facultatively anaerobic. Grows well on nutrient agar containing up to 10% NaCl; growth is very weak in the presence of 15% NaCl. Oxidase and benzidine test positive. Urease variable; arginine dihydrolase, lecithinase, and phosphatase negative; and β-galactosidase variable. Nitrate reduction is negative in most strains. Nitrite reduction negative. No growth occurs on Simmons' citrate agar, and growth does not occur or is weak on inorganic nitrogen agar. Positive for hydrolysis of esculin but negative for hydrolysis of gelatin, Tween 80, and starch. Produces acetoin. Acid is produced aerobically from glucose, fructose, mannose, sucrose, and glycerol and usually from maltose and glucitol. Does not utilize rhamnose, xylose, ribose, arabinose, raffinose, melibiose, mannitol, ribitol, and galactitol; usually does not utilize galactose and lactose. The amino acid and vitamin requirements are complicated. Usually growth is stimulated by leucine, lysine, valine, and tyrosine. Resistant to lysozyme. Susceptible to tetracycline, erythromycin, novobiocin, methicillin, penicillin, kanamycin, chloramphenicol, neomycin, vancomycin, polymyxin B, and streptomycin. Nonhemolytic. The cytochromes are cytochromes aa_3, C_{548}, C_{557}, b_{561}, and d_{626}.

Source: human skin.

DNA G+C content (mol%): 67 (T_m).

Type strain: DSM 20032, ATCC 27570, CCM 2690, CCUG 33026, CIP 81.69, IEGM 390, NBRC 15354, JCM 7237, LMG 14215, NCTC 11038, NRRL B-14835, VKM B-1811.

Sequence accession no. (16S rRNA gene): X80749.

6. **Kocuria marina** Kim, Nedashkovskaya, Mikhailov, Han, Kim, Rhee and Bae 2004, 1619[VP]

ma.ri'na. L. fem. adj. *marina* of the sea.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Gram-positive, aerobic, non-motile, halotolerant coccoid cells. Positive for catalase, β-galactosidase, and urease, but negative for arginine dihydrolase, lysine and ornithine decarboxylase, oxidase, and alkaline phosphatase. Nitrate is reduced, but hydrogen sulfide is not produced. Production of indole and acetoin (Voges–Proskauer reaction) is negative. Growth occurs in the presence of up to 15% NaCl, although its presence is not required for growth. Grows at 4–43°C. Casein, gelatin, and Tween 40 are hydrolyzed, but agar, alginate, cellulose, DNA, starch, Tween 20, and Tween 80 are not. Glucose, lactose, mannose, and sucrose are utilized as sole carbon sources, but not adonitol, L-arabinose, *meso*-inositol, mannitol, sorbitol, citric acid, or malonic acid. Acid is produced from L-fucose, but not from acetic acid, *N*-acetylglucosamine, adonitol, L-arabinose, cellobiose, dulcitol, fumaric acid, galactose, glucose, glycerol, *meso*-inositol, lactose, malic acid, maltose, mannitol, melibiose, raffinose, rhamnose, sorbitol, sorbose, sucrose, and L-xylose. Growth is inhibited by ampicillin, benzylpenicillin, carbenicillin, gentamicin, lincomycin, neomycin, oleandomycin, streptomycin, and tetracycline, but not by kanamycin or polymyxin B.

Source: marine sediment of the Troitsa Bay of the Gulf of Peter the Great, East Siberian Sea.

DNA G+C content (mol%): 60 (method not reported).

Type strain: KMM 3905, DSM 16420, KCTC 9943, CCUG 51442, JCM 13363.

Sequence accession no. (16S rRNA gene): AY211385.

7. **Kocuria palustris** Kovács, Burghardt, Pradella, Schumann, Stackebrandt and Màrialigeti 1999, 171[VP]

pa.lus'tris. L.fem. adj. *palustris* marshy, swampy.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. The cells are spherical (diameter, 1.0–1.5 µm), occurring in pairs, tetrads, and packets, Gram-positive, and non-motile. Endospores not produced. Not acid-fast. The colonies are pale-yellow, 2.0–3.0 mm in diameter, opaque, smooth with irregular edges. Aerobic. Chemoorganotrophic. No growth above 30°C. Good growth between pH 5.7–7.7. Positive for catalase, urease, benzidine, and growth on inorganic nitrogen. Negative for phosphatase, Tween 80 hydrolysis, and esculin hydrolysis. Oxidase, gelatinase, starch hydrolysis, growth on Simmons' citrate, indole, esculin hydrolysis, arginine dihydrolase, and phenylalanine deaminase reaction negative. H_2S reaction weak. Nitrate reduced to nitrite. Acid production from D-glucose, D-fructose, galactose, lactose, and saccharose. No acid production from glycerol, mannitol, sorbitol, ribose, D-xylose, L-arabinose, D-mannose, maltose, β-gentiobiose, D-turanose, arbutin, salicin, trehalose, melezitose, and amidon. Utilization of adonitol, glucuronamide, inosine, Tween 40, and Tween 80. No utilization of cellobiose, turanose, xylitol, methyl-pyruvate, dextrin, glycogen, *N*-acetyl-D-glucosamine, D-trehalose, L-arabinose, D-fructose, L-fucose, *N*-acetyl-D-galactosamine, *m*-inositol, maltose, D-mannitol, D-mannose, D-melibiose, sorbitol, glycerol, L-glutamic acid, and L-alanine not utilized. Growth at 7% NaCl, but no growth at 10% NaCl.

Source: the rhizosphere of *Typha angustifolia* from a floating mat on the Soroksár tributary of the river Danube, Hungary.

DNA G+C content (mol%): 70 (HPLC).

Type strain: TAGA27, DSM 11925, CCUG 52395, CIP 105971, NBRC 16318, JCM 11652.

Sequence accession no. (16S rRNA gene): Y16263.

8. **Kocuria polaris** Reddy, Prakash, Prabahar, Matsumoto, Stackebrandt and Shivaji 2003, 186[VP]

po.la'ris. N.L. fem. adj. *polaris* of or pertaining to a pole.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Cells are coccoid (1.0–1.5 µm in diameter), occur in pairs or tetrads or clusters; non-motile; Gram-positive; aerobic. Colonies on peptone-yeast extract medium were 0.1–2.0 mm in diameter, smooth, round, uniform edged, translucent, extremely mucoid, and orange in color. Psychrotrophic, growing between 5 and 30°C with an optimum at 20°C; cells grow between pH 7 and 12, tolerating up to 2.9% NaCl. Positive for catalase, oxidase, phosphatase, and arginine dihydrolase; negative for urease, lipase, β-galactosidase, hydrolysis of gelatin, esculin, and starch, nitrate to nitrite reduction, indole test, methyl red test, Voges–Proskauer test, and levan formation. Utilizes mannose,

galactose, maltose, fructose, glucose, ribose, xylose, rhamnose, raffinose, trehalose, fumaric acid, dulcitol, inositol, sorbitol, adonitol, sucrose, melibiose, lactose, inulin, pyruvate, acetate, glycine, alanine, leucine, isoleucine, valine, serine, threonine, arginine, and proline; the following substrates were not utilized as the only carbon source: arabinose, succinic acid, citric acid, nicotine, cellulose, cysteine, methionine, lysine, aspartic acid, glutamic acid, asparagine, glutamine, tyrosine, histidine, phenylalanine, and tryptophan. No gas production from glucose, arabinose, xylose, rhamnose, galactose, mannose, lactose, maltose, and sucrose. Sensitive to carbenicillin, tobramycin, chlortetracycline, polymyxin, oxytetracycline, nitrofurantoin, penicillin, bacitracin, nitrofurasone, gentamicin, lincomycin, rifampicin, furazolidone, colistin, furoxone, kanamycin, nystatin, cotrizoxazole, chloramphenicol, ampicillin, tetracycline, amoxicillin, trimethoprim, and erythromycin. Cells contain six water-insoluble pigments which were soluble in methanol; pigment production was not dependent on any specific growth conditions or on the composition of the medium.

DNA G+C content (mol%): 73 (T_m).

Type strain: CMS 76or, DSM 14382, JCM 12076, NBRC 103063, MTCC 3702.

Sequence accession no. (16S rRNA gene): AJ278868.

9. **Kocuria rhizophila** Kovács, Burghardt, Pradella, Schumann, Stackebrandt and Màrialigeti 1999, 172[VP]

rhi.zo′phi.la. Gr. n. *rhiza* a root; Gr. adj. *philos -ê -on* loving; N.L. fem. adj. *rhizophila* root loving.

In addition to the properties given in the genus description and in Table 99, this species has the following characteristics. Cells are spherical, occurring in pairs, tetrads, and packets, 1.0–1.5 µm in diameter, Gram-positive, and non-motile. Endospores not produced. Not acid-fast. The colonies are 1.5–2.5 mm in diameter, opaque, smooth with irregular edges with yellow pigmentation. Aerobic. Chemoorganotrophic. No growth above 40°C. Good growth at pH 5.7–7.7. Catalase, benzidine, and growth on inorganic nitrogen positive. Gelatinase, phosphatase, Tween 80 hydrolysis, growth on Simmons' citrate positive. Oxidase, starch hydrolysis, indole, urease, esculin hydrolysis, arginine dihydrolase, and phenylalanine deaminase reaction negative. H_2S reaction weak. Nitrate not reduced to nitrite. Acid production from D-glucose, D-fructose, D-mannose, and saccharose. No acid production from glycerol, mannitol, sorbitol, ribose, D-xylose, L-arabinose, galactose, lactose, maltose, β-gentiobiose, D-turanose, arbutin, salicin, trehalose, melezitose, and amidon. Utilization of adonitol, L-arabinose, D-fructose, L-fucose, D-glucose, turanose, xylitol, methyl-pyruvate, glucuronamide, dextrin, glycogen, Tween 40, Tween 80, and *N*-acetyl-D-glucosamine. No utilization of cellobiose, D-trehalose, *N*-acetyl-D-galactosamine, *m*-inositol, maltose, D-mannitol, D-melibiose, sorbitol, inosine, glycerol, L-glutamic acid, and L-alanine. Good growth at 10% NaCl.

Source: the rhizosphere of *Typha angustifolia* from a floating mat on the Soroksár tributary of the river Danube, Hungary.

DNA G+C content (mol%): 70 (HPLC).

Type strain: TA68, ATCC BAA-50, CIP 105972, NBRC 16319, JCM 11653, DSM 11926.

Sequence accession no. (16S rRNA gene): Y16264.

10. **Kocuria varians** (Migula 1900) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 690[VP] (*Micrococcus varians* Migula 1900, 135[AL])

va′ri.ans. L. part. adj. *varians* changing, varying.

In addition to the properties given above in the genus description and in Table 99, this species has the following characteristics. Cells are spherical (diameter, 0.9–1.5 µm) and occur in tetrads and irregular clusters of tetrads or rarely in packets or as single cells. Colonies are up to 4 mm in diameter, circular, slightly convex, smooth, and glistening. Some strains may form rough, wrinkled, matt, dry colonies. Colonies are yellow. Does not produce a water-soluble exopigment. Colony morphology and color become more distinct with age; cell morphology is not culture age- or medium-dependent. Slight turbidity and a deposit occur in nutrient broth. Grows well at 22–37°C. The final pH in glucose-containing medium is 4.3–5.9. Growth occurs on nutrient agar containing up to 7.5% NaCl and sometimes on nutrient agar containing 10% NaCl. Growth is stimulated by methionine or cysteine and thiamine. Oxidase test negative; benzidine test positive. Usually positive for urease and nitrate and nitrite reductases; arginine dihydrolase negative. Free and bound coagulase, β-galactosidase, phosphatase, lecithinase, phenylalanine deaminase, and DNase negative. Usually grows on Simmons' citrate agar but not on inorganic nitrogen agar. Negative for hydrolysis of esculin and Tween 80. Hydrolysis of starch and gelatin is variable. Production of acetoin is negative or weak; indole and hydrogen sulfide negative. Acid is produced from glucose, xylose, and fructose, but not from mannose maltose, arabinose, raffinose, galactose, rhamnose, ribitol, lactose, mannitol, glycerol, glucitol, inositol, and salicin. Sucrose utilization is variable. Resistant to lysozyme. Susceptible to kanamycin, neomycin, polymyxin B, and vancomycin; most strains are susceptible to tetracycline, erythromycin, oleandomycin, penicillin G, streptomycin, chloramphenicol, and novobiocin. Very susceptible to methicillin. Nonhemolytic. Saprophytic. The cytochromes are cytochromes aa_3, c_{549}, c_{557}, b_{564}, and d_{626}.

DNA G+C content (mol%): 76.6–72 (T_m).

Type strain: CCM 884, ATCC 15306, DSM 20033, CCUG 35392, CIP 81.73, HAMBI 40, HAMBI 1951, IEGM 400, NBRC 15358, JCM 7238, LMG 14231, NCTC 7564, VKM B-1827.

Sequence accession no. (16S rRNA gene): X87754.

Genus VI. **Nesterenkonia** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689[VP] emend. Collins, Lawson, Labrenz, Tindall, Weiss and Hirsch 2002b emend. Li, Chen, Kim, Zhang, Park, Lee, Xu and Jiang 2005a

Erko Stackebrandt

Ne.ste.ren.ko′ni.a. N.L. fem. n. *Nesterenkonia* honoring Olga Nesterenko, a Ukrainian microbiologist.

Cells may consist of short rods sometimes showing branching, or of cocci. Gram-stain-positive. Non-encapsulated. Endospores are not formed. **Chemo-organotrophic; metabolism is strictly respiratory.** Aerobic. Catalase-positive. Moderately halophilic or halotolerant. Some species are alkaliphilic or alkalitolerant. Mesophilic. **Peptidoglycan type is A4α (L-Lys–Gly–L-Glu, L-Lys–L-Glu or L-Lys–Gly–D-Asp).** Mycolic acids are absent. **Menaquinones with seven, eight, and nine completely unsaturated isoprene units (MK-7, MK-8, and MK-9) predominate.** The phospholipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. The cellular fatty acids are iso and anteiso-branched fatty acids, with $C_{15:0}$ anteiso and $C_{17:0}$ anteiso predominating. Phylogenetically a member of the family *Micrococcaceae*.

DNA G+C content (mol%): 64–72.

Type species: **Nesterenkonia halobia** Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689[VP]; basonym *Micrococcus halobius* Onishi and Kamekura 1972, 235[AL].

Further descriptive information

The phylogenetic intermixing of *Micrococcus* and *Arthrobacter* species was one of the early results of the 16S rRNA oligonucleotide cataloging approach (Stackebrandt and Woese, 1979). This study confirmed studies on the chemotaxonomic heterogeneity of the genus *Micrococcus* (Faller et al., 1980; Girard, 1971; Jeffries, 1969; Morrison et al., 1971). When almost complete 16S rRNA gene sequences became available (Koch et al., 1994), *Micrococcus lylae* was the only species that phylogenetically grouped closely with the type species *Micrococcus luteus*. Lack of close relationship with other *Micrococcus* species could explain the low DNA–DNA hybridization values found between the pairs *Micrococcus luteus* and *Micrococcus varians* and between *Micrococcus luteus* and *Micrococcus kristinae* (Ogasawara-Fujita and Sakaguchi, 1976; Schleifer et al., 1979). Some *Micrococcus* species had been reclassified before or were subsequently reclassified as members of *Deinococcus* (Brooks et al., 1981), *Stomatococcus* (Bergan and Kocur, 1982), and *Arthrobacter* (Koch et al., 1995), or they formed separate phylogenetic lineages which on the basis of chemotaxonomic properties were assigned to the genera *Nesterenkonia* (for *Micrococcus halobius*), *Kocuria* (for *Micrococcus varians*), *Kytococcus* (for *Micrococcus sedentarius*), and *Dermacoccus* (for *Micrococcus nishinomyaensis*) (Stackebrandt et al., 1995). These four genera had different phylogenetic neighbors, the members of which were not always defined by spherical shape (see Stackebrandt and Woese, 1979, and Figure 140 for neighbors of *Nesterenkonia halobia*). Nesterenkonia was affiliated to the family *Micrococcaceae*, suborder *Micrococcineae* (since elevated to order *Micrococcales* in the taxonomic outline to the present volume), order *Actinomycetales* (Stackebrandt et al., 1997). Recently, more species have been added to the genus *Nesterenkonia*, isolated mostly from hypersaline water and soil samples and halophilic and/or slightly alkaliphilic environments: *Nesterenkonia lacusekhoensis* (Collins et al., 2002b), *Nesterenkonia halotolerans*, and *Nesterenkonia xinjiangensis* (Li et al., 2004b), *Nesterenkonia sandarakina*, and *Nesterenkonia lutea* (Li et al., 2005a), *Nesterenkonia aethiopica* (Delgado et al., 2006) while *Nesterenkonia jeotgali* (Yoon et al., 2006) was isolated from jeotgal, a traditional Korean fermented seafood.

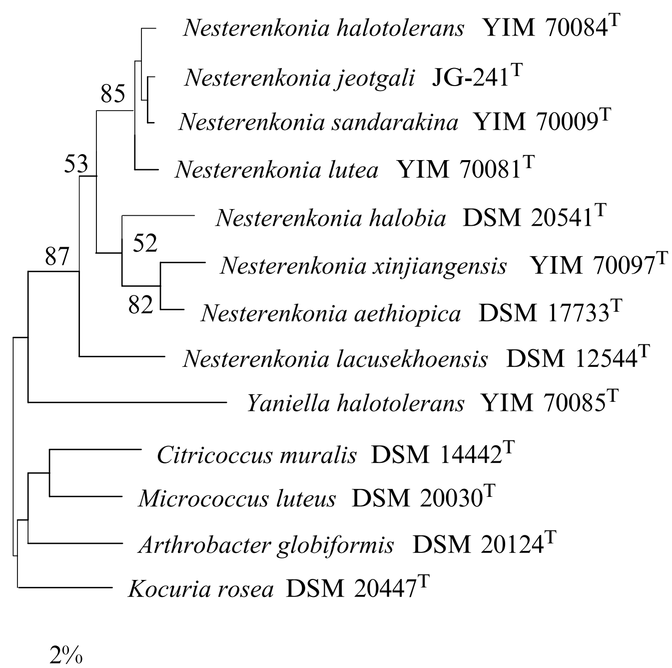

FIGURE 140. Distance matrix tree constructed from 16S rRNA gene sequences (De Soete, 1983) shows the relatedness of the three *Nesterenkonia* species with their nearest neighbors. Bar = 2 inferred nucleotide changes per 100 nucleotides. Numbers on branching points are bootstrap values (1000 resamplings) (Felsenstein, 1985).

Nesterenkonia halobia is the most thoroughly studied species. In all, 150 taxonomic properties of six strains, isolated from ponds of a saltern located in Huelva, Spain (Ventosa et al., 1998) were investigated (Mota et al., 1997). DNA–DNA similarity studies performed among these isolates and the type strain *Nesterenkonia halobia* ATCC 21727[T] revealed 72–100% similarities, confirming the affiliation of the type species. The 16S rRNA gene sequence similarity between *Nesterenkonia halobia* ATCC 21727[T] and one representative of the isolates was 99.1%. Despite the high genomic similarities, differences were found in 9 of the 38 physiological tests also performed on the type strain in the original study of Onishi and Kamegura (1972). The differences were noted in the acid production from some carbohydrates but also in the Voges–Proskauer and Simmons' citrate tests, and hydrolysis of gelatin (Table 100).

Micrographs of *Nesterenkonia halotolerans* and *Nesterenkonia xinjiangensis* (Li et al., 2004b), *Nesterenkonia sandarakina* and *Nesterenkonia lutea* (Li et al., 2005a), and *Nesterenkonia aethiopica* (Delgado et al., 2006) are available as supplementary material in the online publication of these species.

Nesterenkonia spp. have been isolated from various sources and affiliated to described species on the basis of 16S rRNA gene sequences: to *Nesterenkonia lacusekhoensis* for strains from alkaline olive oil extraction waste (Ntougias et al., 2006), to *Nesterenkonia halobia* for strains from decomposing rhizomes of the reed *Phragmites australis* (Borsodi et al., 2005), and a strain from alkaline water of Lake Abijata, Ethiopia (Martins et al., 2001), and to *Nesterenkonia halotolerans* for a strain from an alkaline groundwater environment in Portugal (Tiago et al., 2004).

Enrichment and isolation procedures

Nesterenkonia (*Micrococcus*) *halobia* was isolated from unrefined solar salt of unknown origin obtained from Noda, Japan, in complex medium (Sehgal and Gibbons, 1960) and nutrient broth containing 1 M NaCl. *Nesterenkonia lacusekhoensis* strain IFAM EL-30^T was isolated from a 23 m-deep water sample of Ekho Lake (a hypersaline, meromictic, and heliothermal lake in the ice-free Vestfold Hills, East Antarctica) by means of a Kammerer sampler. The sample was spread directly on plates of medium PYGV (Staley, 1968) agar prepared with Ekho lake water of 10% salinity. Incubation was at 15°C in the dark. *Nesterenkonia sandarakina* YIM 70009^T was isolated from a soil sample collected from the eastern desert of Egypt using a medium containing (g/l): glucose, 10.0; peptone, 5.0; yeast extract, 5.0; $K_2HPO_4 \cdot 3H_2O$, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; Na_2CO_3, 10.0; agar, 15.0. Furthermore, the sodium carbonate and 15% NaCl (w/v) were separately sterilized before addition to the medium. The pH of the medium was 10.0–10.5; $NaHCO_3/Na_2CO_3$ buffer was used to adjust the pH.

Nesterenkonia halotolerans YIM 70084^T and *Nesterenkonia xinjiangensis* YIM 70097^T were isolated from hypersaline soil samples from Xinjiang Province, Western China, using a modified glycerol/asparagine agar (ISP 5) medium (Shirling and Gottlieb, 1966) supplemented with 15% (w/v) $MgCl_2 \cdot 6H_2O$ and KCl, respectively. The isolation plates were incubated at 28°C for 2 weeks. The pH was adjusted to 7.2 with 1 M NaOH. *Nesterenkonia lutea* YIM 70081^T was isolated from a saline soil sample from China using a modified glycerol/asparagine ISP 5 agar medium, supplemented with 15% (w/v) $MgCl_2 \cdot 6H_2O$. Isolation plates were incubated at 28°C for 2 weeks. *Nesterenkonia jeotgali* JG-241^T was isolated by the usual dilution plating technique on marine agar 2216 (MA; Difco) at 30°C. *Nesterenkonia aethiopica* DSM 17733^T originated from a soiled feather sample collected on the shore of Lake Abjata in Ethiopia; cells were enriched and isolated in complex YP medium (Mota et al., 1997) with shaking at 200 r.p.m. at 37°C.

Maintenance procedures

Nesterenkonia halotolerans YIM 70084^T and *Nesterenkonia xinjiangensis* YIM 70097^T are maintained on medium containing 0.1% (w/v) asparagine, 1% glycerol, 0.1% $K_2HPO_4 \cdot 3H_2O$, 0.5% yeast extract, 10% $MgCl_2 \cdot 6H_2O$ (for strain YIM 70084^T), or 10% KCl (for strain YIM 70097^T). *Nesterenkonia sandarakina* YIM 70009^T and *Nesterenkonia lutea* YIM 70081^T were maintained on modified TSA medium containing 5–10% NaCl (w/v), pH 8.0–9.0, or 5–10% $MgCl_2 \cdot 6H_2O$ (w/v), pH 7.0–8.0 for strains YIM 70009^T and YIM 70081^T, respectively. *Nesterenkonia lacusekhoensis* IFAM EL-30^T is maintained on the modified PYGV medium described above, while *Nesterenkonia halobia* is maintained on modified *Corynebacterium* agar (DSM medium 53 containing 6% NaCl) (Catalogue of strains, DSMZ 2001). All strains can also be stored on medium ISP 5, containing the recommended salt (NaCl or KCl) concentration or in the Microbank system (Biolab Diagnostics, Richmond Hill, ON, Canada). For long-term conservation, freeze drying or storage in the vapor phase of liquid nitrogen is recommended.

Taxonomic comments

Sequence analysis of the 16S rRNA gene of the type strains indicates the presence of a phylogenetic closely related species cluster (*Nesterenkonia sandarakina*, *Nesterenkonia jeotgali*, *Nesterenkonia lutea*, *Nesterenkonia halotolerans*, >99.2% similarity). These species possess D-aspartic acid as a diagnostic amino acid in the interpeptide bridge of peptidoglycan. The other species, characterized by D-glutamic acid in the interpeptide bridge of peptidoglycan are more distantly related (>96.1–<97.1% similarity) (Figure 140). The most obvious chemotaxonomic difference between *Nesterenkonia lacusekhoensis* and other species is the lack of a monocarboxylic acid in the interpeptide bridge (lack of glycine). DNA–DNA hybridization values are available for all type strains though not between *Nesterenkonia aethiopica* and *Nesterenkonia jeotgali*, as these species were described in parallel. *Nesterenkonia sandarakina* YIM 70009^T and *Nesterenkonia lutea* YIM 70081^T shared 45.2% similarity, while *Nesterenkonia halotolerans* YIM 70084^T shared 43.3 and 39.1% similarity, respectively, with these type strains (Li et al., 2005a). Using the microtiter plate method of Ezaki et al. (1989), *Nesterenkonia jeotgali* JG-241^T shared 11–53% DNA relatedness with six type strains of the genus. *Nesterenkonia halotolerans*, *Nesterenkonia sandarakina*, and *Nesterenkonia lutea* had the highest DNA relatedness as well as high 16S rRNA gene similarities to *Nesterenkonia jeotgali* JG-241^T (Figure 140). The spectrophotometric hybridization method (De Ley et al., 1970) revealed that *Nesterenkonia aethiopica* DSM 17733^T had the highest reassociation values with *Nesterenkonia lacusekhoensis* DSM 12544^T (57–64%), *Nesterenkonia halobia* DSM 20541^T (49%), and *Nesterenkonia xinjiangensis* DSM 15475^T (29–36%). These values are in accord with sequence similarities between the type strains (Figure 140).

The phylogenetic affiliation of *Nesterenkonia* to the family *Micrococcaceae* is not obvious from Figure 140, which shows the genus branching more closely to *Yania* (Li et al., 2004a), a member of the family *Yaniaceae* (Li et al., 2005b), now the family *Yaniellaceae* (Li et al., 2008b). While according to Li et al. (2005b) *Yania* branches outside the radiation of a few species representing genera that belong to *Micrococcaceae*, this taxon branches within the radiation of *Micrococcaceae* when all species of all genera of the family are included in a phylogenetic analyses (unpublished). In this tree (Figure 140), *Nesterenkonia* and *Yania* are phylogenetic neighbors, raising doubts about the validity of the family *Yaniellaceae*. With respect to chemotaxonomic properties, *Yania* spp. would be compatible with the diversity of the genera of *Micrococcaceae* (Table 101). Irrespective of selection of strains and the treeing algorithm, bootstrap values for the *Nesterenkonia*/*Yania* lineage are low (Li et al., 2005b; Figure 141) and thus the decision on the higher rank of *Yania* has to await additional taxonomic evidence.

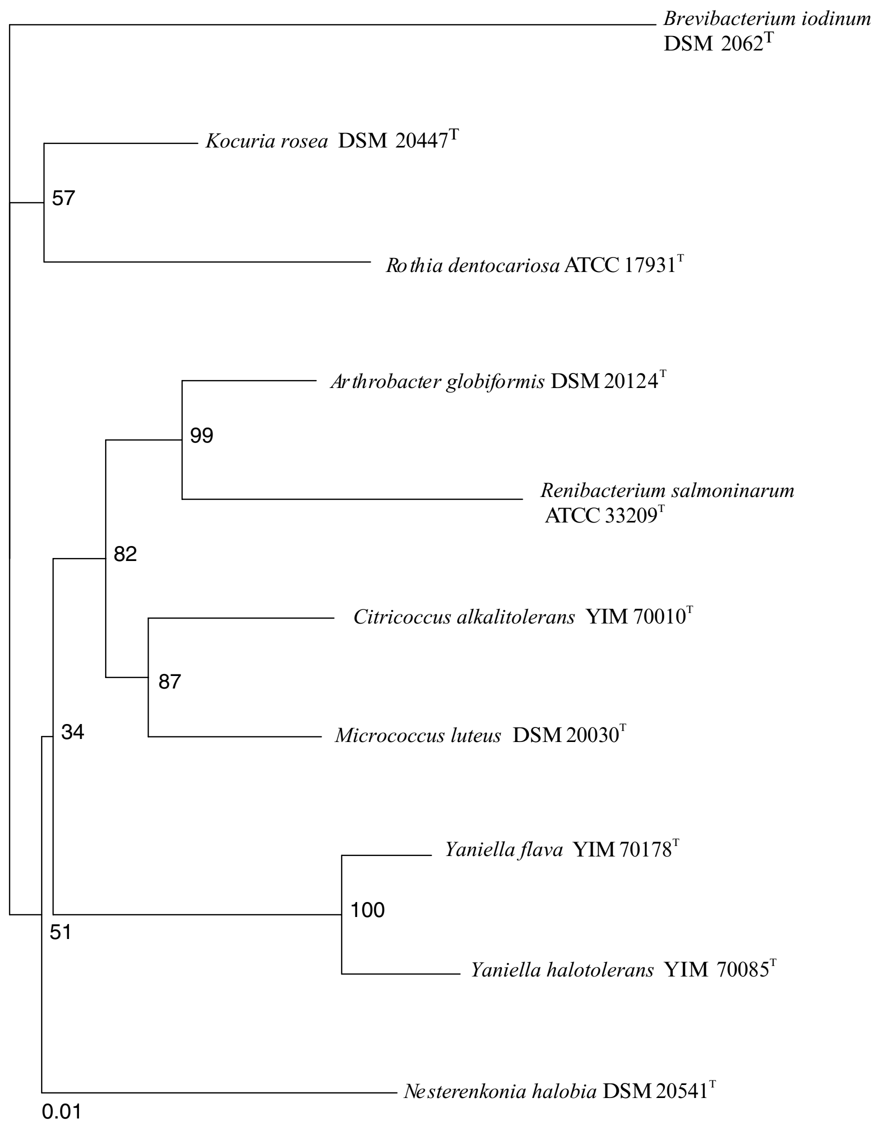

FIGURE 141. 16S rRNA gene sequence neighbor joining tree (Felsenstein, 1993a) of *Yaniella halotolerans* and *Yaniella flava* among representatives of related genera of the order *Micrococcales*. Bootstrap values (>50%) of 1000 resamplings (Felsenstein, 1985) are indicated at nodes. *Brevibacterium iodinum* DSM 2062^T served as root. Bar = 1 nt substitution per 100 nt.

Differentiation of the genus *Nesterenkonia* from other genera

Nesterenkonia, as a member of the family *Micrococcaceae*, differs from other members of the family in morphology, DNA base composition, isoprenoid quinones, and amino acid composition of the peptidoglycan (Table 101). Polar lipid composition distinguishes members of *Nesterenkonia* from *Renibacterium salmoninarum*. The same key properties, especially the DNA G+C content, discriminates *Nesterenkonia* from *Yania*. Affiliation of novel isolates to the genus *Nesterenkonia* should be done on the basis of 16S rRNA gene sequence analysis and from a determination of chemotaxonomic properties, mainly the peptidoglycan type (Table 101). The decision whether to describe novel species should be based on the outcome of studies on the properties listed in Table 100 and Table 101 and, if indicated, by DNA–DNA reassociation studies.

List of species of the genus *Nesterenkonia*

1. **Nesterenkonia halobia** (Onishi and Kamekura 1972) Stackebrandt, Koch, Gvozdiak and Schumann 1995, 689[VP] (Basonym: *Micrococcus halobius* Onishi and Kamekura 1972, 235[AL].)

ha.lo′bi.a. Gr. n. *hals*, *halos* salt; Gr. n. *bios* life, N.L. fem. adj. *halobia* living on salt.

Gram-stain-positive. Cells are coccoid (diameter, 0.8–1.5 μm) occur singly, in pairs, and sometimes in tetrads or irregular clusters. Non-encapsulated. Endospores are not formed. The growth temperature range and optimum are 20–40°C and 37°C, respectively. Optimum growth occurs at pH 7.0–7.5, but strains grow well at pH 5–10. Chemo-organotrophic; metabolism is strictly respiratory. Catalase-positive. Moderately halophilic. Mesophilic. Colonies on nutrient agar supplemented with 5% NaCl are circular, smooth, opaque, and nonpigmented. During growth in nutrient broth, the medium is turbid. Optimum growth occurs on media containing 1–2 M NaCl, moderate growth occurs in the presence of 4 M NaCl, and no growth occurs on media lacking NaCl or KCl. Oxidase test positive. Urease, phosphatase, nitrate reductase, and arginine dihydrolase-negative. Most strains grow on Simmons' citrate agar. Starch, gelatin, casein, esculin, and tyrosine are hydrolyzed, while Tween 80 is not hydrolyzed. Acetoin production is positive; indole and hydrogen sulfide production are negative. Low amounts of acid are produced aerobically from glucose, fructose, and D-xylose. No acid is formed from L-arabinose, D-galactose, glycerol, lactose, maltose, mannitol, sucrose, and trehalose. Utilizes D-tagatose, acetic acid, and *p*-hydroxyphenyl acetic acid but not other substrates provided in the Biolog substrate panel. Milk coagulation occurs without acid formation. Resistant to lysozyme; susceptible to ampicillin (10 μg), bacitracin (10 U), cephalothin (30 μg), chloramphenicol (30 μg), erythromycin (15 μg), novobiocin (30 μg), and rifampin (5 μg). Thiamine is required for growth; growth is stimulated by biotin. Nonhemolytic.

DNA G+C content (mol%): 71–72 (T_m).

Type strain: 28-3, ATCC 21727, DSM 20541, CCM 2591, CCUG 38889, CIP 81.68, NBRC15353, JCM 11483, VKM B-1317.

Sequence accession no. (16S rRNA gene): X80747.

2. **Nesterenkonia aethiopica** Delgado, Quillaguamán, Bakhtiar, Mattiasson, Gessesse and Hatti-Kaul 2006, 1232[VP.]

a.e.thio′pi.ca. L. fem. adj. *aethiopica* pertaining to Ethiopia.

Cells are Gram-stain-positive, nonmotile, non-capsule-forming, non-endospore-forming, short rods around 0.7 μm in width and 1.2 μm in length. Catalase- and oxidase-positive and urease-negative. Strictly aerobic and mesophilic: exhibits good growth at 25–40°C, with an optimum between 30 and 37°C; unable to grow at 45°C. Alkaliphilic and moderately halophilic. Optimal growth occurs at initial pH 9 (range pH 7–11) and at 3% (w/v) NaCl (range 3–12%). Carbohydrates utilized as sole carbon sources are D-glucose, D-fructose, and other sugars listed in Table 100. Acid is produced in medium supplied with D-glucose, D-fructose, L-arabinose, and glycerol, but acidification is not detected with D-trehalose, D-galactose, D-lactose, D-mannitol, or D-xylose. Starch, casein, tyrosine, and gelatin are hydrolyzed. Indole is not produced and the Voges–Proskauer test is negative.

DNA G+C content (mol%): 69.0 (HPLC).

Type strain: DSM 17733, CCUG 48939, JCM 14309.

Sequence accession no. (16S rRNA gene): AY574575.

3. **Nesterenkonia halotolerans** Li, Chen, Zhang, Schumann, Stackebrandt, Xu and Jiang 2004b, 838[VP]

ha.lo.to′le.rans. Gr. n. *hals*, *halos* salt, L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating, referring to the ability to tolerate high salt concentrations.

Cells are Gram-stain-positive, non-spore-forming, motile cocci. The colony color on modified ISP 5 medium is deep orange–yellow (the color of the fringe) to light orange–yellow (the color of the center); some colonies resemble concentric rings. Colonies are circular, opaque, and approximately 2.5–3.5 mm in diameter after 24 h at 28°C. The optimum growth temperature is 28°C. The optimum concentration of $MgCl_2 \cdot 6H_2O$ is 10%. The type strain is positive for gelatin liquefaction and urease production and negative for milk peptonization and coagulation, nitrate reduction, growth on cellulose, H_2S and melanin production, and starch hydrolysis. Positive for catalase, milk coagulation, melanin production, growth in cellulose, and lysine decarboxylase, β-glucosidase, β-galactosidase, and α-maltosidase activities. Negative for indole production, decomposition of Tween 20 and Tween 80, casein and starch, and ornithine decarboxylase, arginine dihydrolase, and *N*-acetylglucosaminidase activities. Maltose, glucose, galactose, mannose, fructose, sucrose, maltose, starch, lactose, dextrin, mannitol, and salicin are utilized as sole carbon sources for growth. Rhamnose, acetamide, inositol, adonitol, ribose, arabinose, cellobiose, trehalose, sorbitol, and xylose are not utilized.

Source: a saline soil sample from Xinjiang Province, China.

DNA G+C content (mol%): 64 (T_m).

Type strain: YIM 70084, CCTCC AA001022, DSM , JCM 13018.

Sequence accession no. (16S rRNA gene): AY226508.

4. **Nesterenkonia jeotgali** Yoon, Jung, Kim, Nam and Oh 2006, 2591[VP]

je.ot.ga′li. N.L. gen. n. *jeotgali* of jeotgal, from which the type strain was isolated.

Cells are cocci (diameter 0.5–0.8 μm) on marine agar (MA) at 30°C; some cells are oval in the very early growth phase. Non motile. Colonies are smooth, circular, slightly convex or raised, glistening and 1.0–2.0 mm in diameter after 5 d cultivation at 30°C on MA. Colonies on MA are vivid yellow in color at 30°C, but orange–yellow in color at 25°C. Colonies on solid PYGV medium are light yellow in color at 25 and 30°C. Optimal growth temperature is 25–30°C; growth occurs at 4 and 36°C, but not at 37°C. Optimal pH for growth is 7.5–8.5; growth occurs at pH 6.0, but not at pH 5.5. Optimal growth occurs in the presence of 2–5% (w/v) NaCl; growth occurs in the presence of 0–16% NaCl (w/v). Growth does not occur under anaerobic conditions on MA or on MA supplemented with nitrate. Voges–Proskauer reaction positive. Indole production negative. Tyrosine is hydrolyzed, but esculin, casein, gelatin, hypoxanthine, starch, xanthine, and Tweens 20, 40,

60, and 80 are not hydrolyzed. Nitrate is not reduced. Methyl red reaction is positive. In assays with the API ZYM system, alkaline phosphatase, esterase (C4), esterase lipase (C8), α-glucosidase, and leucine arylamidase are present, but lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, ornithine decarboxylase, and tryptophan deaminase are absent. D-glucose, D-galactose, L-arabinose, D-cellobiose, D-fructose, maltose, sucrose, acetate, citrate, succinate, L-malate, and pyruvate are utilized. Benzoate, salicin, formate, and L-glutamate are not utilized. Acid is produced from L-arabinose, D-cellobiose, D-glucose, maltose, D-mannose, D-melezitose, D-ribose, and sucrose, but not from D-fructose, melibiose, D-raffinose, L-rhamnose, *myo*-inositol, or D-sorbitol. Susceptible to penicillin G, chloramphenicol, ampicillin, cephalothin, novobiocin, and carbenicillin, but not to polymyxin B, gentamicin, kanamycin, or neomycin.

Source (type strain): jeotgal, a traditional Korean fermented seafood.

DNA G+C content (mol%): 68.0 (HPLC).

Type strain: JG-241, KCTC 19053, JCM 12610.

Sequence accession no. (16S rRNA gene): AY928901.

5. **Nesterenkonia lacusekhoensis** Collins, Lawson, Labrenz, Tindall, Weiss and Hirsch 2002b, 1149[VP]

la.cus.ek.ho.en′sis. N.L. fem. adj. *lacusekhoensis* of or belonging to Ekho Lake, the lake in Antarctica from which the organism was isolated.

Cells consist of short rods with a mean size of 0.8–1.2 μm; sometimes branching is observed. In older cultures, cocci predominate. Cells are nonmotile and do not contain poly β-hydroxybutyrate granules. Colonies show a bright yellow pigmentation. Thiamine HCl is required, and nicotinic acid and biotin stimulate growth. The optimal temperature for growth is 27–33.5°C, and the optimal pH is 8.6. DNA is hydrolyzed, but Tween 80, starch, and alginate are not. Cells form sulfide but not indole. Methyl-red-negative and Voges–Proskauer-negative. Nitrate is not reduced anaerobically. Metabolizes sugars, sugar alcohols and some organic acids.

Source: hypersaline, heliothermal, and meromictic Ekho Lake (23 m) in East Antarctica.

DNA G+C content (mol%): 66.0 (HPLC).

Type strain: IFAM EL-30, DSM 12544, CIP 107030, CCUG 47141, JCM 11953.

Sequence accession no. (16S rRNA gene): AJ290397.

6. **Nesterenkonia lutea** Li, Chen, Kim, Zhang, Park, Lee, Xu and Jiang 2005a, 465[VP]

lu′te.a. L. fem. adj. *lutea* gold–yellow.

Cells are Gram-stain-positive, non-spore-forming, motile cocci with flagella. Colony color on most tested media is light yellow to primrose yellow. Colonies are circular, opaque, somewhat convex and approximately 0.5–1.0 mm in diameter after 24 h at 28°C. Growth occurs at 0–20% (w/v) $MgCl_2 \cdot 6H_2O$ (optimum at 5–10%, w/v) and pH 6.5–10.0 (optimum at 7.0–8.0). Positive for catalase, milk coagulation, melanin production, growth in cellulose, and lysine decarboxylase, β-glucosidase, β-galactosidase, and α-maltosidase activities. Negative for indole production, decomposition of Tween 20 and Tween 80, casein and starch, and ornithine decarboxylase, arginine dihydrolase, and *N*-acetylglucosaminidase activities. Maltose, sucrose, mannitol, salicin, and galactose are utilized as sole carbon sources for growth; rhamnose, acetamide, inositol, adonitol, and sorbitol are not utilized.

Source: a saline soil sample from the Xinjiang Province, China.

DNA G+C content (mol%): 65.0 (T_m).

Type strain: YIM 70081, CCTCC AA 203010, DSM 15666, KCTC 19013, JCM 13019.

Sequence accession no. (16S rRNA gene): AY588278.

7. **Nesterenkonia sandarakina** Li, Chen, Kim, Zhang, Park, Lee, Xu and Jiang 2005a, 464[VP]

san.da.ra′ ki.na. N.L. fem. adj. *sandarakina* (from Gr. fem. adj. *sandarakinê*) of orange color.

Cells are Gram-stain-positive, non-spore-forming cocci. Colony color on most tested media is orange–yellow. Colonies are circular, opaque, and approximately 0.5–1.0 mm in diameter after 24 h at 28°C. Growth occurs at 1–15% (w/v) NaCl (optimum at 5%, w/v) and pH 5.0–12.0 (optimum at 8.0–9.0). Positive for catalase, milk coagulation, melanin production, growth in cellulose, and lysine decarboxylase, β-glucosidase, β-galactosidase, and α-maltosidase activities. Negative for indole production, decomposition of Tween 20 and Tween 80, casein and starch, and ornithine decarboxylase, arginine dihydrolase, and *N*-acetylglucosaminidase activities. Maltose, sucrose, mannitol, salicin, and galactose are utilized as sole carbon sources for growth; rhamnose, acetamide, inositol, adonitol, and sorbitol are not utilized.

Source: a soil sample collected from the eastern desert of Egypt.

DNA G+C content (mol%): 64.0 (T_m).

Type strain: CCTCC AA 203007, DSM 15664, KCTC 19011 JCM 13020, YIM 70009.

Sequence accession no. (16S rRNA gene): AY588277.

8. **Nesterenkonia xinjiangensis** Li, Chen, Zhang, Schumann, Stackebrandt, Xu and Jiang 2004b, 840[VP]

xin.ji.ang.en′sis. N.L. fem. adj. *xinjiangensis* of or pertaining to Xinjiang, the province of western China in which the samples were collected.

Cells are Gram-stain-positive, nonmotile, non-spore-forming, diphtheroid, irregular rods. The colony color on modified ISP 5 medium is light yellow. Colonies are circular, opaque, somewhat convex and approximately 3.5–4.5 mm in diameter after 24 h at 28°C. The optimum growth temperature is 28°C. The optimum concentration of KCl for growth is 10.0%. The type strain is positive for gelatin liquefaction, milk peptonization, and urease production and negative for milk coagulation, nitrate reduction, growth in cellulose, H_2S and melanin production and starch hydrolysis. Almost all tested carbon sources, including glucose, galactose, mannose, fructose, sucrose, maltose, starch, lactose, dextrin, ribose, arabinose, cellobiose, and xylose, are utilized; trehalose and sorbitol are not utilized.

Source: a saline soil sample from Xinjiang Province, China.

DNA G+C content (mol%): 67.0 (T_m).

Type strain: YIM 70097, CCTCC AA001025, DSM 15475, JCM 13021.

Sequence accession no. (16S rRNA gene): AY226510.

Genus VII. **Renibacterium** Sanders and Fryer 1980, 501[VP]

Brian Austin (updated from J.E. Sanders and J.L. Fryer, 1986)

Re.ni.bac.te′ri.um. L. pl. n. *renes* the kidneys; L. neut. n. *bacterium* rod; N.L. neut. n. *Renibacterium* kidney bacterium.

Short rods or **cocco-bacilli**, 0.3–1.0 × 1.0–1.5 µm, often occurring in pairs (= diplococcobacilli) and short chains. **Strongly Gram-stain-positive**. Nonencapsulated. Nonmotile. Endospores are absent.

Aerobic, slow-growing bacterium; temperature for optimum growth 15–18°C; no growth at 37°C. Cysteine required for growth. Growth enhanced by addition of blood, serum (especially fetal calf serum), or charcoal to media. **No acid production from sugars. Catalase-positive. The cell-wall peptidoglycan contains D-alanine**, **D-glutamic acid, glycine, and lysine as the diamino acid.** Cell-wall sugars include galactose, rhamnose, *N*-acetylglucosamine, and *N*-acetylfucosamine. No mycolic acids are present. The major fatty acid is 12-methyltetradecanoic acid ($C_{15:0}$) with 14-methylhexadecanoic acid ($C_{17:0}$ anteiso) also present in significant amounts. The major respiratory quinones are unsaturated menaquinones with nine isoprene units.

DNA G+C content (mol%): 53 (T_m).

Type species: **Renibacterium salmoninarum** Sanders and Fryer 1980, 501[VP].

Further descriptive information

Uniquely stained "bar" forms have been observed *in vivo*, but have never been cultured (Cvitanich, 2004). Cells grown in culture media tend to exhibit consistent, uniform morphology whereas pleomorphic forms may be observed among cells from fish tissues (Fryer and Sanders, 1981).

Enrichment and isolation procedures

Renibacterium may be isolated from diseased fish by streaking diseased kidney tissue onto Mueller–Hinton medium supplemented with 0.1% (w/v) L-cysteine hydrochloride (Wolf and Dunbar, 1959), KDM-2 medium* (Evelyn, 1977), SKDM† (Austin et al., 1983) or charcoal agar‡ (Daly and Stevenson, 1985). Peptone (0.1% w/v)-saline (0.85% w/v) has been recommended as a diluent to remove potentially inhibitory compounds, which may be present in kidney tissue (Evelyn et al., 1981). A "nurse" culture technique based on satellitism or cross feeding enhances recovery of the pathogen, and involves inoculating drops of a dense suspension of a stock culture of *Renibacterium salmoninarum* (= nurse organism) onto the center of isolation media. Then, 25-µl drops of material containing renibacteria are placed around the periphery of the nurse organism (Evelyn et al., 1989). Recovery of *Renibacterium salmoninarum* may be further improved by supplementing the isolation medium with small amounts of spent broth used previously for growing the organism. Here, it is thought that unknown metabolites serve as growth stimulants for the renibacteria (Evelyn et al., 1989, 1990). Inoculated media in Petri dishes should be sealed in containers/bags to prevent loss of moisture, and incubated at 15–18°C. Growth of *Renibacterium* on these media at primary isolation may be slow, and depending on the state of the infection, the size of the inoculum and the nature of the medium may require up to 19 weeks for visible colonies to develop (Benediktsdóttir et al., 1991). Nurse cultures develop more rapidly, i.e. ≥7 d faster than cultures by conventional plating methods. Laboratory cultures may require several weeks of incubation before colonies appear.

On non-selective media, the presence of contaminants may overgrow the organism. The presence of antibiotics in SKDM improves the recovery of *Renibacterium* from diseased fish tissues (Austin et al., 1983; Benediktsdóttir et al., 1991). Also, dropplating reduces problems with contamination (Evelyn et al., 1990).

Shake cultures in KDM-2 broth give uniform growth throughout the medium. However, initial attempts at growth in broth are often characterized by a prolonged lag period; subsequent transfers often reduce this period substantially.

Mueller–Hinton medium supplemented with 0.1% (w/v) L-cysteine hydrochloride has also been used for the growth of *Renibacterium* (Bullock et al., 1974; Wolf and Dunbar, 1959). However, Evelyn (1971) indicated that serum appears to be an essential ingredient for the isolation and continued cultivation of *Renibacterium*. Paterson et al. (1979) added 10% (v/v) fetal calf serum to cysteine supplemented Mueller–Hinton to improve primary isolation. A semi-defined culture medium devoid of serum has been reported for the routine laboratory cultivation of *Renibacterium*, especially for the preparation of biomass for chemical analyses (Embley et al., 1982).

Pathogenicity. Koch's postulates were initially fulfilled by Ordal and Earp (1956) who monitored mortality after infecting chinook salmon by intraperitoneal injection. Murray et al. (1992) succeeded in inducing disease in chinook salmon by immersing them in 10^4–10^6 cells/ml for 15–30 min and by co-habitation of healthy with other experimentally infected fish. The pathogen becomes internalized in non-phagocytic cells (González et al., 1999) and macrophages that produce virulence factors (McIntosh et al., 1997). Within phagocytic cells, the pathogen divides slowly, and survives for >10 d (Gutenberger et al., 1997). An alternative view is that respiratory burst products generated by macrophages kill renibacteria (Campos-Pérez et al., 1997; Hardie et al., 1996).

A hydrophobic, soluble cell surface p57 protein is responsible for agglutination of salmonid leukocytes (Senson and Stevenson, 1999; Wiens et al., 1999), and is encoded by *msa* (major soluble antigen) genes (Coady et al., 2006, 2004; Rhodes et al.,

---

*KDM-2 medium contains 1.0% (w/v) peptone, 0.05% (w/v) yeast extract, 0.1% (w/v) L-cysteine hydrochloride, 1.5% (w/v) agar; pH 6.5; sterilized at 121°C for 15 min, cooled to 45°C, then 20% (v/v) sterile fetal calf serum is added.

†SKDM medium contains 1.0% (w/v) tryptone, 0.05% (w/v) yeast extract, 0.005% (w/v) cycloheximide, 1.0% (w/v) agar; pH 6.8; sterilized at 121°C for 15 min, cooled to 50°C, and then sterile fetal calf serum is added to 10% (v/v), and filter-sterilized solutions of L-cysteine hydrochloride (0.1% w/v), D-cycloserine (0.00125% w/v), polymyxin B sulfate (0.0025% w/v), and oxolinic acid (0.00025% w/v).

‡Charcoal agar contains 1.0% (w/v) peptone, 0.05% (w/v) yeast extract, 0.1% (w/v) L-cysteine hydrochloride, 0.1% (w/v) activated charcoal, 1.5% (w/v) agar; pH 6.8; sterilized at 121°C for 15 min (the charcoal may be placed in dialysis tubing prior to sterilization to obtain a clear broth medium).

[g]Data from Li et al. (2004a, 2005c).

2002). A possible role for extracellular products (ECP) in the pathogenicity process is unclear. Some workers have reported the presence of proteases (Sakai et al., 1989) and hemolysins (Grayson et al., 1995a, 2001) in ECPs with the mode of action reflecting inhibition of the respiratory burst but not phagocytic activity in spleen phagocytes (Densmore et al., 1998). Hydrophobicity and auto-aggregation have been linked with virulence (Bruno, 1988). An iron acquisition mechanism has been found (Grayson et al., 1995b). There is evidence that fish respond to infection by the production of stress factors, including plasma cortisol and lactate, and reduced levels of plasma glucose (Mesa et al., 1999). In particular, a 70-kDa stress protein (HSP70) has been recognized in diseased coho salmon (Forsyth et al., 1997).

Maintenance procedures

Renibacterium cultures may be lyophilized by common procedures used for many bacteria. Broth cultures supplemented with 15–20% (v/v) glycerol as cryopreservant may be frozen at −70°C, and maintain viability for one year or longer.

Differentiation of the genus *Renibacterium* from other genera

For routine diagnosis, serological methods, including co-agglutination (Kimura and Yoshimizu, 1981), Western blots (Lovely et al., 1994), the fluorescent antibody test, and the enzyme linked immunosorbent assay (Griffiths et al., 1996, 1991; Jansson et al., 1996; Kozinska and Pekala, 2005; O'Connor and Hoffnagle, 2007; Pascho et al., 1998), have been useful, although cross-reactions have been recorded with coryneforms, a fish pathogenic *Mycobacterium* sp., *Rothia dentocariosa* (Austin and Rayment, 1985), *Pseudomonas* (Yoshimizu et al., 1987), and other unidentified bacteria (Brown et al., 1995; Bullock et al., 1980). The polymerase chain reaction (PCR) amplifying a 320-bp fragment of a 57-kDa protein (p57 antigen; Pascho et al., 1998), nested reverse transcriptase PCR (Cook and Lynch, 1999), quantitiative PCR Powell et al., 2005), real-time PCR (Chase et al., 2006 ; Suzuki and Sakai, 2007), sequencing of the 16S rRNA gene (Konigsson et al., 2005), and terminal restriction fragment length polymorphism (Nilsson and Strom, 2002) are specific and sensitive.

Renibacterium may be distinguished from all other genera in the *Micrococcaceae* (Table 102) (by the requirement for cysteine and preference for serum, low optimum growth temperature, i.e. 15–18°C, and comparatively lengthy time necessary for the development of visible colonies. *Renibacterium* has a distinctive API ZYM profile after incubation for 24 h at 18°C (Austin et al., 1983). Strains are positive for alkaline phosphatase, caprylate esterase, leucine arylamidase, trypsin, acid phosphatase, phosphoamidase, α-glucosidase, and α-mannosidase (+/−), and negative for butyrate esterase, myristate lipase, valine arylamidase, cystine arylamidase, chemotrypsin, α-galactosidase, β-galactosidase, β-glucuronidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-fucosidase.

Taxonomic comments

Prior to the description of *Renibacterium*, the organism was linked with *Brevibacterium* (Smith, 1964), *Corynebacterium* (Sanders et al., 1978), *Lactobacillus* (Vladik et al., 1974), *Listeria* (Bullock et al., 1975) and *Rickettsia* (Snieszko and Griffin, 1955). By 16S rRNA cataloging, *Renibacterium salmoninarum* was considered to comprise a member of the actinomycete subdivision, being related to *Arthrobacter*, *Brevibacterium*, *Cellulomonas*, *Jonesia*, *Micrococcus*, *Promicromonospora*, *Stomatococcus*, and *Terrabacter* (Gutenberger et al., 1991; Stackebrandt et al., 1988). This was supported by Grayson et al. (2000), who linked *Renibacterium* to the high-G+C group of the actinobacteria, notably *Arthrobacter*, on the basis of rRNA gene sequence comparisons (Grayson et al., 2000). The organism has been included in the family *Micrococcaceae* (Stackebrandt and Schumann, 2000a).

A low genetic diversity has been concluded from the results of analysis of 44 enzymes and 40 renibacterial isolates from North America by multilocus enzyme electrophoresis leading to the recognition of 21 electrophoretic types (Starliper, 1996).

List of species of the genus *Renibacterium*

1. **Renibacterium salmoninarum** Sanders and Fryer 1980, 501[VP]

sal.mo.ni.na′rum. N.L. pl. n. *Salmoninae* subfamily of the *Salmonidae*; N.L. gen. pl. n. *salmoninarum* of the *Salmoninae*.

Short rods, cocco-bacilli, 0.3–1.0 × 1.0–1.5 µm, often occurring in pairs (diplococcobacilli) and short chains. May be pleomorphic, and contain intracellular granules. Strongly Gram-stain-positive. Not acid-fast. Nonmotile. Nonencapsulated. Endospores absent. Hemolysis not observed.

On cysteine serum agar, KDM-2 and SKDM media, colonies are circular and convex, white to creamy yellow, and 2 mm in diameter after ~20 d. Old cultures, i.e. ≥12 weeks, may become extremely granular or crystalline in appearance, and a transverse section will reveal the presence of a few Gram-stain-positive rods embedded in a crystalline matrix. Subculturing at this stage often leads to the development of more crystalline "colonies". On Loeffler coagulated serum, a creamy growth with a matt surface is produced, and with Dorset egg medium, growth appears as a raised, smooth shiny yellow layer (Smith, 1964). Creamy yellow growth occurs only at the surface in stationary cultures in cysteine serum broth. Growth on all media is slow, especially at primary isolation, often requiring up to 19 weeks for visible colonies.

Grows very slowly at 5 and 22°C; no growth at 37°C (Smith, 1964). Optimal growth occurs at 15–18°C. Maximum cell yields with laboratory cultures are obtained after 20–30-d incubation at 15–18°C and pH 6.5–7.5 (Fryer and Sanders, 1981).

Aerobic. No acid production from sugars. Does not reduce nitrate. Produces acid and alkaline phosphatase, caprylate esterase, α-glucosidase, leucine arylamidase, and α-mannosidase, but not butyrate esterase, cystine arylamidase, α-fucosidase, α- or β-galactosidase, β-glucosaminidase, β-glucosidase, β-glucuronidase, myristate esterase, or valine arylamidase (Goodfellow et al., 1985). Utilizes 4-umbelliferyl-acetate, 4-umbelliferyl–butyrate, 4-umbelliferyl-heptanoate, 4-umbelliferyl–laurate, 4-umbelliferyl-nonanoate, 4-umbelliferyl–oleate and 4-umbelliferyl–propionate (Goodfellow et al., 1985). All strains isolated require cysteine, and the majority require serum, whole blood, or charcoal for growth. Catalase-positive. Cytochrome-oxidase-negative. Degrades casein, tributyrin, Tween 40, and 60, but not adenine, esculin, arbutin, chitin, chondroitin, DNA, elastin, gelatin, guanine, hyaluronic acid, hypoxanthine, lecithin, RNA, starch, testosterone, Tween 80, tyrosine, or xanthine (Goodfellow et al., 1985).

The cell-wall peptidoglycan contains D-alanine, D-glutamic acid, glycine, and lysine as the diamino acids (Fiedler and Draxl, 1986). The structure contains a glycylalanine interpeptide bridge and the substitution of the α-carboxyl group of D-glutamic acid in position 2 of the peptide subunit with D-alanineamide (Kusser and Fiedler, 1983). Sanders and Fryer (1980) reported the principal cell-wall sugar as glucose, although arabinose, mannose, and rhamnose are also present. However, subsequently, Kusser and Fiedler (1983) demonstrated that the principal cell-wall sugar is galactose, with lesser amounts of *N*-acetylglucosamine, rhamnose, and *N*-acetyl-fucosamine. Methyl-branched fatty acids form over 92% of the total fatty acid component of the cells, with 12-methyltetradecanoic acid (C_{15}) and 14-methylhexadecanoic (C_{17}) as the major components (Embley et al., 1983). The principal respiratory quinones are unsaturated menaquinones with nine isoprene units (Collins, 1982). Straight chain fatty acids generally account for 1% of the total fatty acids, and unsaturated fatty acids are not detected at all. Over 81% of the total fatty acids are composed of the lower melting point anteiso acids, which may contribute to membrane fluidity at low temperatures. All strains contain diphosphatidylglycerol, two major and six or seven minor glycolipids and two unidentified minor phospholipids (Embley et al., 1983). Mycolic acids are absent (Fryer and Sanders, 1981).

Renibacterium salmoninarum is considered to be serologically homogeneous (Bullock et al., 1974; Getchell et al., 1985), although two serogroups have been subsequently described (Bandín et al., 1992).

Renibacterium salmoninarum is an obligate fish pathogen causing a disease known as bacterial kidney disease, Dee disease, and corynebacterial/salmonid kidney disease. The pathogen occurs intracellularly, especially in macrophages (McIntosh et al., 1997) and produces a slowly developing chronic infection characterized by the presence of gray-white enlarged necrotic abscesses primarily in the kidney (Fryer and Sanders, 1981; Wood and Yasutake, 1956). External signs include bilateral exophthalmia, melanosis, and abdominal distension with ascites. There may be blood filled blisters on the flank, and abscesses (Austin and Austin, 2007). Infections develop over a range of water temperatures (4–20.5°C; Sanders et al., 1978). The pathological changes in the fine structure of both the glomerulus and renal tubules of the kidney resemble those observed in mammalian glomerulonephritis and nephritic syndrome (Young and Chapman, 1978). *Renibacterium salmoninarum* is shed from fish feces, and survives in the aquatic environments for short periods of up to 1 week (Balfry et al., 1996).

By disk diffusion, cultures are sensitive to bacitracin, chloramphenicol, cycloserine, erythromycin, terramycin, novobiocin, streptomycin, nitrofurazone, and sulfonamides. *In vivo* tests have indicated that erythromycin gives the best results; however, when this compound is removed from diets the disease quickly reappears (Austin, 1985; Brown et al., 1990; Evelyn et al., 1986; Lee and Evelyn, 1994; Wolf and Dunbar, 1959).

Occurs among populations of mostly farmed and rarely wild salmonid fish in North and South America, Europe, Iceland, and Japan. Has been found mostly in members of the subfamily Salmoninae, i.e. salmon, trout, and char, of the family Salmonidae. There is one report of clinical disease in ayu (*Plecoglossus altivelis*; Nagai and Iida, 2002) and sea lamprey (*Petromyzon marinus*; Eissa et al., 2006).

DNA G+C content (mol%): 53±1.0 (T_m).

Type strain: Lea-1-74, ATCC 33209, CIP 103036, DSM 20767, NBRC15589, JCM 11484, LMG 10846.

Other strains: ATCC 33739 (81-10B-E-BK), NCIMB 1111 (SUND), NCIMB 1112 (CHAT), NCIMB 1113 (CRAW), NCIMB 1114 (1085), NCIMB 1115 (1086) and NCIMB 1116 (TS30).

Sequence accession no. (16S rRNA gene): AF093461 and AF180950.

Genus VIII. **Rothia** Georg and Brown 1967, 68[AL]

Brian Austin (updated from Mary Ann Gerencser and George H. Bowden, 1986)

Roth′i.a. N.L. fem. n. *Rothia* named for Genevieve D. Roth, who performed basic studies with these organisms.

Coccoid, spherical, **dipththeroid, filamentous** mycelial cells, usually up to 1.0 µm in diameter. Irregular swellings and clubbed ends up to 5.0 µm in diameter may be present. Growth may be exclusively coccoid, diphtheroid, or filamentous or a mixture of these forms. **Gram-stain-positive**. Nonmotile. Endospores are absent. Non acid-fast. Mature colonies (4–7 d) 2–6 mm in diameter, usually off-white/cream, smooth or rough, usually soft in texture but may be dry and crumbly or mucoid. **Optimum temperature for growth is 30–37°C.** Usually catalase-positive**. Chemo-organotrophic.** Ferments carbohydrates. **Major product of glucose fermentation is lactic acid. Does not produce propionic acid. The cell-wall peptidoglycan type is A3α, and contains alanine, glutamic acid, and lysine**, but not **diaminopimelic acid (DAP).** Contains **MK-7** as the major isoprenoid quinone. Cell-wall sugars include **fructose**, **galactose**, and **glucose**, but not **6-deoxy-talose** or **arabinose.**

DNA G+C content (mol%): 54–60 (T_m).

Type species: **Rothia dentocariosa** (Onishi 1949) Georg and Brown 1967, 68[AL].

Further descriptive information

Growth may consist entirely of coccoid, diphtheroidal, filamentous, or mycelial forms, but mixtures of these cell types are more common. Filamentous forms are seen in cultures grown on solid media whereas coccoid forms are more common in broth cultures. Mycelial forms are composed of branched filaments, which fragment into bacillary or coccoid forms (Daneshvar et al., 2004). Cells in 2- to 3-d-old broth cultures may be entirely coccoid, but it is difficult to maintain a culture in the coccoid form. Occasional diplo-coccoid forms occur (Daneshvar et al., 2004).

Lai and Listgarten (1980) described the cell wall as a moderately electron-dense layer, 19–32 nm thick. Multiple cleavage planes parallel to each other and to the cell surface gave the impression of a multilayered cell wall. Markedly thickened segments of cell-wall material were seen also. No periplasmic space was observed. When grown on blood agar, the contour of the wall was rough. Neither long nor short surface fuzz or other structures were present outside the cell wall. Mesosomes or intracellular membrane intrusions and electron-dense-cytoplasmic inclusions were present. Nucleoids were seen in cells grown in broth, but not on agar. No variation in the wall structure at the ultrastructural level was found in the various morphological types.

Young, i.e. 18–24 h, colonies grown anaerobically are microscopic and usually highly filamentous, frequently resembling the "spider" colonies of *Actinomyces*. Young colonies grown aerobically are larger, i.e. ≥1 mm in diameter, smooth or granular, and may or may not have a fringed border.

Older colonies, i.e. 4–7 d old, may be smooth and convex, or have rough, highly convoluted (folded) but glistening surfaces. The texture may be creamy, dry, crumbly, or mucoid.

Rothia grows well on brain heart infusion agar (BHIA), tryptone soya agar (TSA) and on nutrient agar. The best growth occurs aerobically at 30–37°C, but some growth occurs anaerobically in an atmosphere of N_2:H_2:CO_2 (80:10:10). Little or no growth is obtained on media with inorganic nitrogen, such as Czapek. Citrate does not serve as the sole source of carbon for energy and growth.

Rothia has a fermentative metabolism, producing mainly lactic and acetic acid from glucose. The lactate dehydrogenase (LDH) produced by *Rothia* is activated by fructose 1,6-diphosphate, and inhibited by adenosine 5′-triphosphate, and thus resembles the LDH of *Actinomyces viscosus* (Eisenberg et al., 1976).

Enrichment and isolation procedures

The culture media recommended for primary isolation and maintenance are BHIA and TSA with incubation aerobically at 37°C for 2–7 d. *Rothia amarae* and *Rothia terrae* grow well in Luria–Bertani broth. Selective media have been described for the isolation of *Rothia* (Beighton, 1976; Beighton and Colman, 1976; Ritz, 1966).

Pathogenicity. Rothias, notably *Rothia dentocariosa* and *Rothia mucilaginosa*, are commonly found in the human oral cavity and the pharynx, respectively (Collins et al., 2000; Schaal, 1992; Yang et al., 2007). Although regarded as having low virulence to humans particularly children (Yang et al., 2007), *Rothia dentocariosa* is associated with dental plaque and periodontal disease (Binder et al., 1997; Yang et al., 2007) and opportunistic diseases, i.e. endocarditis, endophthalmitis, peritonitis, septicemias, and other serious infections including those of immunocompromised and intensive care patients (Bibashi et al., 1999; Binder et al., 1997; Boudewijns et al., 2003; Ergin et al., 2000; Ferraz et al., 1998; Kong et al., 1998; Lee et al., 2008; Martínez-Martínez, 1998; Minato and Abiko, 1984; Nguyen et al., 2000; Pape et al., 1979; Pers et al., 1987; Salamon and Prag, 2002; Schafer et al., 1979; Schiff and Kaplan, 1987; Vaccher et al., 2007). There is evidence that *Rothia dentocariosa* occurs in infections which may lead to complications or be associated with other medical conditions, for example, pneumonia in an immunocompromised patient with lung cancer (Wallet et al., 1997), vertebral osteomyelitis complicating endocarditis (Llopis and Carratala, 2000), endocarditis in a child with congenital heart disease (Braden et al., 1999), endocarditis in patients with periodontal disease and endocarditis, multiple brain abscesses and severe heart failure in another patient with periodontal disease (Binder et al., 1997), endocarditis in association with multiple cranial hemorrhages (Ricaurte et al., 2001), and renal disease (Habib et al., 1999). In some cases, oral surgery is associated with infection, for example, *Rothia dentocariosa* was recovered from a patient with endocarditis complicated by multiple cerebellar hemorrhages (Sadhu et al., 2005). Also, *Rothia dentocariosa* has been recovered from a child with endophthalmitis (Partner et al., 2006) and a child having a corneal ulcer and the oropharynx was thought to be the source of infection (Morley and Tuft, 2006). In the latter case, the organism in saliva may have been transferred via fingers (Morley and Tuft, 2006).

Other pediatric infections involving *Rothia dentocariosa* include severe acute tonsillitis characterized by a thick white membrane covering the tonsils, leukocytosis, and elevated C-protein level (Ohashi et al., 2005), septicemia in the absence of endocarditis in a neonatal infant with meconium aspiration syndrome (Shin et al., 2004), and sepsis in a renal transplant patient (Wiesmayr et al., 2006). *Rothia dentocariosa* isolates forming charcoal-black pigmented colonies have been recovered from the female genitourinary tract (Daneshvar et al., 2004).

Rothia mucilaginosa has been reported as an opportunistic cause of meningitis leading to death in seriously immunocompromised pediatric patients with malignant tumors or undergoing hematopoietic stem cell transplantation (Lee et al., 2008). Also, the organism has been associated with bacteremia in patients with Shwachman-Diamond syndrome and cancer/leukemia (Fanourgiakis et al., 2003; Paci et al., 2000; Vaccher et al., 2007), with lower respiratory tract infections including pneumonia and recurrent lung abscesses (Korsholm et al., 2007) and AIDS (Cunniffe et al., 1994). It has been associated with meningitis/central nervous system infections (Goldman et al., 1998; Skogen et al., 2001) in immunocompromised patients with cancer and immunocompromised recipients of hematopoietic stem cell transplants (Goldman et al., 1998; Lee et al., 2008).

Abscess formation has been documented in experimental studies in mice (Miksza-Zylkiewicz and Linda, 1980; Roth and Flanagan, 1969; Scharfen, 1975).

Maintenance procedures

Cultures on BHIA or TSA slopes remain viable for 3–4 months at room temperature. For long-term storage, suspensions should be lyophilized.

Procedures for testing special characters

Microcolonies of *Rothia* are best demonstrated by dropping a sterile coverslip over a portion of the inoculum on a BHIA plate with incubation aerobically at 35°C for 18–24 h. Microcolonies will be filamentous under the coverslip, and smooth outside the coverslip (Roth and Thurn, 1962).

In general, methods described for testing biochemical characteristics of *Actinomyces* spp. are suitable for *Rothia* except that aerobic incubation is important. The catalase test is best performed by flooding growth on slopes with 3.0% H_2O_2, and observing for effervescence (a positive test). Anaerobic cultures need to be exposed to air for 15–30 min before testing.

A satisfactory fermentation base medium is 3 g of meat extract, 10 g of peptone, 5 g of NaCl, 10 ml of Andrade's indicator, and 1000 ml of distilled water. The oxidative-fermentative test (Hugh and Leifson, 1953) is useful for differentiating *Rothia* from *Nocardia*, which oxidizes or does not utilize glucose in this medium. Degradation of gelatin may be detected and evaluated in gelatin agar (BHIA supplemented with 4 g of gelatin/l). After 7 d of incubation, the plates are flooded with saturated ammonium sulfate, and observed for the development of clear zones around the bacterial growth. For chemotaxonomic analysis, *Rothia* is best grown in bulk in tryptone soya broth or nutrient broth on a shaker.

Differentiation of the genus *Rothia* from other genera

Rothia may be differentiated from all other genera in the family *Micrococcaceae* by the G+C content of the DNA and the menaquinone content (see Table 100 and Table 102). The distinguishing traits between *Rothia* spp. have been included in Table 103.

Taxonomic comments

The genus *Rothia* was created to accommodate organisms originally regarded as *Nocardia* (Davis and Freer, 1960; Roth, 1957; Roth and Thurn, 1962) and assigned to the family *Actinomycetaceae* (Roth, 1957; Schaal, 1992). These organisms are normal inhabitants of the mouth and throat. On the basis of molecular studies, the genus was reassigned to the family *Micrococcaceae* (Stackebrandt et al., 1997). *Stomatococcus mucilaginosus* (Bergan and Kocur, 1982) was reclassified as *Rothia mucilaginosa* after 16S rRNA gene sequencing and whole-cell protein analysis (Collins et al., 2000). *Rothia nasimurium* was described to accommodate isolates from the nose of a mouse (Collins et al., 2000); *Rothia aeria* was found in the air from the Russian space station, Mir (Li et al., 2004c). *Rothia amarae* was recovered from sludge (Fan et al., 2002) and *Rothia terrae* was isolated from soil (Chou et al., 2008). *Rothia* resembles *Actinomyces* morphologically but grows better aerobically. Only one study (Schofield and Schaal, 1981) reported stimulation of growth by CO_2.

List of species of the genus *Rothia*

1. **Rothia dentocariosa** (Onishi 1949) Georg and Brown 1967, 68[AL] (*Actinomyces dentocariosa* Onishi 1949, 282)

den.to.car.i.o′sa. L. n. *dens, dentis* tooth; L. adj. *cariosus -a -um* decayed or decaying; N.L. fem. adj. *dentocariosa* tooth-decaying.

Produces off white/cream colonies of 2–6 mm in diameter after 4–7 d. Cells (usually 1.0 μm in diameter) are nonmotile, Gram-stain-positive, coccoid, diphtheroid, filamentous, or mycelial. In addition, isolates form charcoal-black pigmented colonies (Daneshvar et al., 2004).

Aerobic to microaerophilic. No or very poor growth anaerobically. CO_2 is not required for growth. Possesses a fermentative metabolism. Optimum growth at 35–37°C. Catalase variable. Produces acetic and lactic acid, trace amounts of pyruvic and succinic acids, but no butyric, caproic, isovaleric, or propionic acid from glucose fermentation. Reduces nitrate and nitrite. The results of indole production are contradictory. The Voges–Proskauer reaction is positive. Produces acid from fructose, glucose, maltose, salicin, sucrose, and trehalose but not adonitol, amygdalin, cellobiose, dulcitol, erythritol, glycogen, inositol, inulin, mannitol, α-methyl-D-mannoside, melibiose, raffinose, sorbitol, starch, or xylose. Produces leucine aminopeptidase, trypsin, and α-glucosidase, but not alkaline phosphatase, chemotrypsin, α- and β-galactosidase, β-glucoronidase, lipase (C_{14}), α-mannosidase, phosphoamidase, or β-xylosidase. Degrades esculin and usually gelatin, but not albumin, casein, starch, or urea. No hemolysis on human and sheep blood, but variable hemolysis on rabbit blood. Grows in 2% (w/v) sodium chloride, 5% and 10% (w/v) bile, 0.01% (w/v) potassium tellurite, 0.005% (w/v) sodium azide, 0.01% (w/v) sodium selenite, and 0.2% (w/v) sodium taurocholate but not 6% (w/v) sodium chloride and 0.05% (w/v) crystal violet (Holmberg and Hallander, 1973; Kilian, 1978; Miksza-Zylkiewicz, 1980; Schofield and Schaal, 1981; Slack and Gerenscer, 1975).

Characterized by the presence of iso- even-numbered fatty acids and only anteiso- odd-numbered fatty acids. Specifically, $C_{15:0}$ anteiso, C_{16}; $C_{16:0}$, and $C_{17:0}$ anteiso fatty acids are present with only trace amounts of other fatty acids. The peptidoglycan is of the A3α type with D-alanine and L-lysine in position 4 and 3, respectively and L-alanine in the interpeptide bridge (Von Graevenitz, 2004). The polar lipids are mono- and di-phosphatidylglycerol and the major isoprenoid quinone is MK-7. The cell wall contains fructose, galactose, glucose, and ribose (Embley et al., 1984; Hammond, 1970a; Von Graevenitz, 1999).

Heterogeneity has been recognized within the species on the basis of phenotype and serotyping (Lesher et al., 1974), pyrolysis mass spectrometry (Sutcliffe et al., 1997), and 16S rRNA gene sequencing (Kronvall et al., 1998), with the resulting delineation of two phenotypically indistinguishable genomovars that do not correspond to biotypes (Kronvall et al., 1998); the second of these genomovars was elevated to a new species, *Rothia aeria*.

Using antiserum to killed whole cells of *Rothia* for serotyping by immunofluorescence, *Rothia* was separated into at least three serovars. However, some isolates failed to react with any of the available antisera (Lesher et al., 1974). This suggests the existence of additional serovars.

Hammond (1970a) isolated a soluble polysaccharide antigen from the cell wall with a major antigenic determinant containing fructose, glucose, galactose, and ribose. This antigen was found in all strains of *Rothia* tested, and may account for the cross-reactions seen between serovars.

The G+C content of the DNA reported by Hammond (1970b) was questioned by Gustafson et al. (1985), who determined the value for the type strain ATCC 17931 as 53.7–54.7 ±0.43 mol%, with a slightly different result for ATCC 19426. The compromise suggested by Gustafson et al. (1985) was a value for the species of 54–57 mol%.

DNA G+C content (mol%): 54–57 (T_m).

Type strain: ATCC 17931, CCUG 35437, CIP 81.83, DSM 43762, DSM 46363, NBRC 12531, JCM 3067, NCTC 10917, NRRL B-8017.

Sequence accession no. (16S rRNA gene): M59055.

2. **Rothia aeria** Li, Kawamura, Fujiwara, Naka, Liu, Huang, Kobayashi and Ezaki 2004c, 833[VP]

a.e′ri.a. L. fem. adj. *aeria* of the air, referring to the isolation of the type strain from the air in the Russian Mir space station.

Young colonies are creamy white and smooth and become rough, dry, folded, convex, and adherent to the agar surface with age. Cells are Gram-stain-positive coccoid, coccobacillary, or filamentous. Growth occurs on BHIA at 30°C. Catalase-positive. Does not produce alkaline phosphatase. Utilizes arbutin, dextrin, D-fructose, α-hydroxybutyric acid, L-lactic acid, maltose, maltotriose, D-mannose, D-melezitose, 3-methyl glucose, glycerol, methyl-α-D-glucoside, α-D-glucose, methyl-β-D-glucoside, palatinose, D-psicose, salicin, sucrose, D-trehalose, and turanose but not acetic acid, *N*-acetyl D-glucosamine, *N*-acetyl L-glutamic acid, *N*-acetyl D-mannosamine, adenosine, adenosine 5′-monophosphate, alaninamide, L- or D-alanine, L-alanyl glycine, amygdalin, L-arabinose, D-arabitol, L-asparagine, 2,3-butanediol, cellobiose, α- and β-cyclodextrin, 2′-deoxyadenosine, L-fructose, fructose 6-phosphate, D-galactose, D-galacturonic acid, gentiobiose, D-gluconic acid, glucose 1-phosphate, glucose 6-phosphate, L-glutamic acid, DL-α-glycerol phosphate, glycogen, glycyl L-glutamic acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenyl acetic acid, *m*-inositol, inosine, inulin, α-ketoglutaric acid, α-ketovaleric acid, D-lactic acid methyl ester, lactamide, α-D-lactose, lactulose, D- and L-malic acid, D-mannitol, D-melibiose, methyl α-D-galactoside, methyl-β-D-galactoside, methyl-α-D-mannoside, methyl pyruvate, mannan, monomethyl succinate, propionic acid, L-pyroglutamic acid, pyruvic acid, putrescine, D-raffinose, L-rhamnose, D-ribose, sedoheptulosan, L-serine, D-sorbitol, stachyose, succinamic acid, succinic acid, D-tagatose, thymidine, thymidine 5′-monophosphate, Tween 40 or 80, uridine, uridine 5′-monophosphate, xylitol, or D-xylose (Li et al., 2004c).

The cell-wall peptidoglycan is the A3α type. The predominant isoprenoid quinone is MK-7. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. The major polar lipids are phosphatidylglycerol and cardiolipin (Li et al., 2004c).

The species includes cultures formerly recognized as *Rothia dentocariosa* genomovar II.

The 16S rDNA sequence similarities with *Rothia dentocariosa*, *Rothia mucilaginosa*, *Rothia amarae*, and *Rothia nasimurium* were 98.0, 96.4, 96.0, and 95.4%, respectively.

Source (type strain): air in the Russian space laboratory, Mir.
DNA G+C content (mol%): 57 (T_m).
Type strain: A1-17B, DSM 14556, JCM 11412, GTC 867.
Sequence accession no. (16S rRNA gene): AB071952.

3. **Rothia amarae** Fan, Jin, Tong, Li, Pasciak, Gamian, Liu and Huang 2002, 2259[VP]

a.ma′ra.e. Gr. n. *amara* trench, conduit, channel; here a sewage duct; N.L. gen. n. *amarae* of a sewage duct.

Produces cream, mucoid, smooth, convex colonies, which roughen with age. Cells are nonmotile, Gram-stain-positive, and ovoid to spherical (0.6–0.9 μm in diameter) and occur either singly, in pairs, tetrads, or packets. Facultatively anaerobic; grows well aerobically, but only poorly anaerobically. Grows optimally at 30–37°C, and not at all at 15 and 45°C. Catalase-positive. Reduces nitrate to nitrite. Produces acid from glucose, glycerol, maltose, mannose, ribose, salicin, sucrose, and trehalose but not lactose, mannitol, raffinose, or sorbitol. Produces ester lipase C8 and valine arylamidase both weakly, but not phosphatase, trypsin, and urease. Degrades esculin and gelatin (Fan et al., 2002). The cell-wall peptidoglycan type is A3α. Phosphatidylglycerol and diphosphatidylglycerol are the main phospholipids and phosphatidylinositol is a minor component. The major isoprenoid quinones are MK-6(H_2) and MK-7. The major cellular fatty acid is $C_{15:0}$ anteiso (Fan et al., 2002). The 16S rDNA sequence similarities with *Rothia dentocariosa*, *Rothia mucilaginosa*, and *Rothia nasimurium* were 96.0, 96.7, and 97.3%, respectively.

Source: sludge (regarded as deodorized dung and sewage) in a foul water sewer in China.
DNA G+C content (mol%): 54.5 (T_m).
Type strain: J18, JCM 11375, AS 4.1721, CCUG 47294.
Sequence accession no. (16S rRNA gene): AY043359.

4. **Rothia mucilaginosa** (Bergan and Kocur 1982) Collins, Hutson, Båverud and Falsen 2000, 1250[VP] (*Stomatococcus mucilaginosus* Bergan and Kocur 1982, 374)

mu.ci.la.gi.no′sa. L. fem. adj. *mucilaginosa* slimy.

Colonies (1–1.5 mm in diameter) are mucoid, transparent or whitish, adherent, convex, non-hemolytic with entire edges on blood agar. Cells are Gram-stain-positive, encapsulated, nonmotile, facultatively anaerobic, non-sporeforming cocci (0.9–1.3 μm in diameter) and are arranged mostly in clusters and occasionally in pairs and tetrads. Growth occurs optimally at 30–37°C but not at all on nutrient agar supplemented with 5% (w/v) NaCl. Catalase is weakly positive or negative. Acid is produced from fructose, glucose, glycerol, maltose, mannose, sucrose, salicin and trehalose, but not from adonitol, lactose, mannitol, raffinose, sorbitol, or xylose. Simmons' citrate is not utilized. The Voges–Proskauer reaction is positive. Nitrates are reduced to nitrite. Esculin and gelatin are degraded, but not DNA, starch, Tween 80, tyrosine, or urea. Arginine, H_2S, indole, coagulase, lysine and ornithine decarboxylase, oxidase, and phosphatase are not produced (Bergan and Kocur, 1982; Stackebrandt et al., 1983a). The dominant fatty acids are C_{15} and C_{16}. The cell wall contains peptidoglycan of the L-Lys–L-Ser$_2$–D-Glu type. Mannose containing lipoglycan is present rather than lipoteichoic acid (Sutcliffe and Old, 1995). The major glycolipid is dimannosyl acylmonoglyceride (Pasciak et al., 2004).

DNA G+C content (mol%): 56–60.4 (T_m).
Type strain: CCUG 20962, ATCC 25296, NCTC 10663, CCM 2417, CIP 71.14, DSM 20746, NBRC 15673, JCM 10910.
Sequence accession no. (16S rRNA gene): X87758.

5. **Rothia nasimurium** Collins, Hutson, Båverud and Falsen 2000, 1250[VP]

na.si.mu′ri.um. L. n. *nasus* nose; L. gen. pl. n. *murium* of mice; N.L. pl. gen. n. *nasimurium* of the nose of mice.

Growth occurs aerobically and in 5% CO_2 on Columbia blood agar base supplemented with 5% (v/v) defibrinated horse blood at 37°C. Colonies are non-pigmented and cells are facultatively anaerobic, Gram-stain-positive, nonmotile, and ovoid. Catalase-positive. Weakly α-hemolytic, and degrades esculin but not sodium hippurate. Reduces nitrate. The Voges–Proskauer reaction is negative. Produces acid from glucose, lactose, maltose, methyl-β-D-glucopyranoside, sucrose, and trehalose, but not from L-arabinose, D-arabitol, cyclodextrin, glycogen, mannitol, melibiose, melezitose, *N*-acetylglucosamine, pullulan, raffinose, ribose, sorbitol, tagatose, or D-xylose. Produces alanine-phenylalanine-proline arylamidase, cystine arylamidase, ester lipase C8, β-galacturonidase, α-glucosidase, leucine arylamidase, valine arylamidase, pyrazinamidase, and trypsin, but not alkaline phosphatase, arginine dihydrolase, esterase C4, α-fucosidase, α-galactosidase, β-glucosidase, β-glucuronidase, lipase C14, α- and β-mannosidase, or urease (Collins et al., 2000). The main cellular fatty acids are iso- and anteiso-methyl branched types with $C_{15:0}$ predominating. The 16S rRNA gene sequence revealed 96.6% similarity to both *Rothia dentocariosa* and *Rothia mucilaginosa*.

6. **Rothia terrae** Chou, Chou, Lin, Lin, Wei, Arun, Young and Chen 2008, 87[VP]

ter′ra.e. L. gen. n. *terrae* of the earth, i.e. the organism was isolated from soil.

Colonies are white/cream colored. Cells are aerobic, spherical to ovoid (0.5–1.5 × 0.5–1.0 μm) and occur singly, in pairs, or tetrads. Fermentative, with poor growth occurring in anaerobic conditions. Growth occurs at 15–40°C, optimally at 35°C, in 0–7% (w/v) NaCl (optimally in 0–0.5% [w/v] NaCl) and at pH 7.0–8.0. Poly-β-hydroxybutyrate granules do not accumulate intracellularly. Catalase-positive. The Voges–Proskauer reaction is positive. Nitrate is reduced. H_2S is not produced. Esculin and gelatin are hydrolyzed, but not casein, starch, Tween 20, 40, 60, or 80, or urea. Produces alkaline phosphatase, esterase C4, β-galactosidase, α- and β-glucosidase, leucine arylamidase, lipase C8, naphthol-AS-B1-phosphohydrolase, and pyrazinamidase but not *N*-acetyl-β-glucoaminidase, acid phosphatase, α-chemotrypsin, α-fucosidase, α-galactosidase, β-glucuronidase, cysteine arylamidase, lipase C14, α-mannosidase, pyrrolidonyl arylamidase, trypsin, or valine arylamidase. Acid is produced from fructose, glucose, glycerol, lactose, maltose, mannose, sucrose, and trehalose but not adonitol, glycogen, mannitol, ribose, salicin, or xylose. Glycerol, 3-methylglucose, D-psicose, L-lactic acid, and methylpyruvate are

oxidized, but 2,3-butanediol, DL-α-glycerol phosphate, α-hydroxybutyric acid, malic acid, methyl-α-D-glucoside, methyl-β-D-glucoside, monomethyl succinate, pyruvic acid, salicin, and succinic acid are not. Dextrin, D-fructose, α-D-glucose, glycerol, glycogen, maltose, D-mannose, 3-methyl-D-glucose, L-lactic acid, D-lactic acid methyl ester, D-psicose, pyruvic acid methyl acid, L-serine, sucrose, D-trehalose, and turanose are utilized in the Biolog GP2 system, but not acetic acid, *N*-acetyl-D-glucosamine, *N*-acetyl-L-glutamic acid, *N*-acetyl-β-D-mannosamine, adenosine, adenosine-5′-monophosphate, L-alaninamide, D- and L-alanine, L-alanylglycine, amygdalin, L-arabinose, D-arabitol, arbutin, L-asparagine, 2,3- butanediol, D-cellobiose, α- or β-cyclodextrin, 2′-deoxyadenosine, D-fructose 6-phosphate, L-fucose, D-galactose, D-galacturonic acid, gentiobiose, α-D-glucose 1-phosphate, α-D-glucose 6-phosphate, L-glutamic acid, DL-α-glycerol phosphate, glycyl-L-glutamic acid, α-, γ-and β-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, inosine, *myo*-inositol, inulin, α-ketoglutaric acid, α-ketovaleric acid, lactamide, α-D-lactose, lactulose, L- and D-malic acid, maltotriose, mannan, D-mannitol, D-melezitose, D-melibiose, α-and β-methyl-D-galactoside, α- and β-methyl-D-glucoside, α-methyl-D-mannoside, palatinose, propionic acid, L-pyroglutamic acid, putrescine, pyruvic acid, D-raffinose, L-rhamnose, D-ribose, salicin, sedoheptulosan, D-sorbitol, stachyose, succinamic acid, succinic acid, succinic acid monomethyl ester, D-tagatose, thymidine, thymidine-5′-monophosphate, Tween 40 and 80, uridine, uridine-5′-monophosphate, xylitol, or D-xylose. Resistant to gentamicin, kanamycin, and nalidixic acid, but not to ampicillin, chloramphenicol, erythromycin, novobiocin, penicillin G, rifampin, streptomycin, or tetracycline (Chou et al., 2008). The peptidoglycan type is A3α and contains alanine, glutamic acid, and lysine. Phosphatidylglycerol and diphosphatidylglycerol are the main phospholipids and some unknown glyco- and phospholipids are minor components. The predominant fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{16:0}$. The major isoprenoid quinone is MK-7.

Source: soil in Taiwan.

DNA G+C content (mol%): 56.1 ± 0.5 (T_m).

Type strain: L-143, BCRC 17588, LMG 23708.

Sequence accession no. (16S rRNA gene): DQ822568.

Genus IX. **Yaniella** (Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a) Li, Zhi and Euzéby 2008b, 526[VP] (Illegitimate homotypic synonym: *Yania* Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a, 529)

Peter Schumann

Ya.ni.el′la. N.L. fem. dim. n. *Yaniella* named after Sun-Chu Yan (1912–1994), a Chinese microbiologist who devoted his life to the study of actinomycete taxonomy and antibiotics.

Cells are nonmotile, aerobic, Gram-stain-positive, nonsporeforming, coccoid or oval, about 0.4–0.8 µm in diameter, and occur singly or in clusters. Moderately **halophilic or halotolerant**. **Oxidase negative** and **catalase positive**. Cell-wall peptidoglycan **type** is **A4α**, **L-Lys←Gly←L-Glu**. Whole-cell sugars are xylose, mannose, and galactose. Phospholipids are diphosphatidylglycerol, phosphatidylglycerol, one unknown phospholipid, and one unknown glycolipid. Predominant **menaquinones** are **MK-8 and MK-9 or MK-8**. Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso or $C_{15:0}$ anteiso. The description is based on those of the species *Yaniella halotolerans* (Li et al., 2004a) and *Yaniella flava* (Li et al., 2005c).

DNA G+C content (mol%): 53–58.

Type species: **Yaniella halotolerans** (Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a) Li, Zhi and Euzéby 2008b, 526[VP] (*Yania halotolerans* Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a, 530).

Further descriptive information

The genus *Yaniella* was established to harbor two isolates from geographically distant saline habitats in China which showed less than 94.3% 16S rRNA gene sequence similarity to their phylogenetic neighbors (Li et al., 2004a, 2005c). Due to the low 16S rRNA gene sequence similarity to other members of the suborder *Micrococcineae*, the family *Yaniellaceae* with *Yaniella* as type genus was proposed by Li et al. (2005c). A phylogenetic study of type species of all genera of the suborder *Micrococcineae* (subsequently expanded and elevated to order *Micrococcales* in the taxonomic outline to the present volume) revealed that the genus *Nesterenkonia* in the family *Micrococcaceae* was the closest phylogenetic neighbor of the genus *Yaniella* (Figure 140, *Nesterenkonia* chapter, above). The type strains of *Yaniella halotolerans* and *Yaniella flava* show 98.4% 16S rRNA gene sequence similarity at a bootstrap value of 100%. Their DNA–DNA similarity is only 35.4%, and both type strains can be differentiated by a set of species-specific phenotypic properties (Li et al., 2005c; Table 104). The cells of both type strains are Gram-stain-positive nonmotile cocci. The peptidoglycan type is A4α, L-Lys←Gly←L-Glu (A11.56 according to http://www.peptidoglycan-types.info). The menaquinones MK-8 (83%), MK-7 (12%), and MK-9 (1.5%) occur in *Yaniella halotolerans* while *Yaniella flava* contains the menaquinones MK-8, MK-9, and MK-7 in the ratio 64:29:1. The cellular fatty acid profile of *Yaniella halotolerans* consists of $C_{15:0}$ iso (44.3%), $C_{15:0}$ anteiso (35.6%), $C_{17:0}$ anteiso (9.7%), $C_{15:0}$ (0.3%), $C_{16:0}$ (0.9%), $C_{14:0}$ iso (1.5%), $C_{16:0}$ iso (3.3%), $C_{17:0}$ iso (2.8%), $C_{19:0}$ anteiso (0.4%), $C_{16:1}$ ω7*c* (0.5%), and $C_{15:1}$ iso (0.7%), while that of *Yaniella flava* contained $C_{15:0}$ anteiso (58.2%), $C_{14:0}$ iso (12.5%), $C_{15:1}$ iso (9.3%), $C_{16:0}$ iso (8.0%), $C_{17:0}$ anteiso (5.8%), $C_{13:0}$ iso (2.1%), $C_{17:0}$ iso (1.9%), $C_{16:0}$ (0.6%), $C_{15:1}$ anteiso (0.5%), $C_{13:0}$ anteiso (0.4%), $C_{16:1}$ ω7*c* (0.3%), $C_{18:1}$ ω9*c* (0.3%), and $C_{14:0}$ (0.1%). The polar lipid pattern of *Yaniella halotolerans* contained traces of phosphatidylinositol in addition to the pattern consisting of diphosphatidylglycerol, phosphatidylglycerol, one unknown phospholipid, and one unknown glycolipid shared by both species. The colonies of strains YIM 70085[T] and YIM 70178[T] on ISP5 agar supplemented with 10% KCl (w/v) are light yellow, circular, lubricous, and opaque. Both type strains grow optimally at pH 7.0–8.0 and at salt concentrations of 10–15% KCl, NaCl, or $MgCl_2{\cdot}6H_2O$ under aerobic conditions.

Enrichment and isolation procedures

Yaniella halotolerans YIM 70085[T] was isolated by using the dilution plating method from a saline soil sample from Xinjiang

TABLE 104. Characteristics differentiating *Yaniella halotolerans* YIM 70085[T] and *Yaniella flava* YIM 70178[T,a,b]

Characteristic	*Y. halotolerans* strain YIM 70085[T]	*Y. flava* strain YIM 70085[T]

[b]Data from Zhang et al. (2007) and Tang et al. (2009).

[c]Data from Stackebrandt and Schumann (2000a), Liu et al. (2000), and Wieser et al. (2002).

[d]*Arthrobacter globiformis* group is defined here as containing predominantly dihydrogenated menaquinones and a peptidoglycan with monocarboxyl amino acids only in the interpeptide bridge (peptidoglycan type A3α) or with a D-aspartate. The definition of this group is not in line with that given by Keddie et al., (1986) for the *Arthrobacter globiformis/citreus* group. Data from Keddie et al. (1986), Kodama et al. (1992), Koch et al. (1995), Stackebrandt et al. (1995), Funke et al. (1996), and Heyrman et al. (2005).

[e]*Arthrobacter nicotianae* group is defined here as containing only quinones with unsaturated isoprenoid units in the side chain and a peptidoglycan with a dicarboxyl amino acid (glutamic acid) in the interpeptide bridge (peptidoglycan type A4α). The definition of this group is not in line with that given by Keddie et al., (1986) for *Arthrobacter nicotianae* group. Data from Collins and Kroppenstedt (1983), Keddie et al. (1986), Koch et al. (1995), Stackebrandt et al. (1995), Funke et al. (1996), Gupta et al. (2004), Margesin et al. (2004), and Chen et al. (2005a).

[f]*Arthrobacter cumminsii/albus* group is here defined as containing dihydrogenated menaquinone with eight isoprenoid units in the side chain [MK-8(H_2)] and a peptidoglycan with a dicarboxyl amino acid (glutamic acid) in the interpeptide bridge (A4α). Data from Funke et al. (1996), Wauters et al. (2000a), and Busse, unpublished results.

[g]Altenburger et al. (2002) and Li et al. (2005b).

[h]Pukall et al. (2006).

[i]Parentheses indicate variation among species or strains.

Province, west China. The medium used for selective isolation was glycerol/asparagine agar (ISP 5 medium: 1.0 g L-asparagine, 10.0 g glycerol, 1.0 g K_2HPO_4, 1.0 ml trace salts solution, and 20.0 g agar per 1000 ml distilled water; Shirling and Gottlieb, 1966) that was supplemented with 15% KCl (w/v). *Yaniella flava* YIM 70178^T was isolated by dilution plating on SGA agar (7.5 g Casamino acids, 10.0 g yeast extract, 20.0 g $MgSO_4 \cdot 7H_2O$, 3.0 g sodium citrate, 2.0 g KCl, 1.0 ml trace salts solution, and 15.0 g agar per 1000 ml distilled water, pH 7.5–7.6; Al-Tai and Ruan, 1994) supplemented with 20% KCl (w/v) from a saline soil sample originating from Qinghai Province in north-west China. The trace salts solution for both strains consisted of 0.1g $FeSO_4 \cdot 7\ H_2O$, 0.1g $MnCl_2 \cdot 4\ H_2O$, and 0.1g $ZnSO_4 \cdot 7\ H_2O$ per 1000 ml distilled water, pH 7.0–7.4. Both strains were obtained from cultures incubated at 28°C for 2 weeks. Biomass for chemical and molecular systematic studies was obtained by cultivation in shaken flasks (about 150 rpm) of modified ISP5 broth (KCl 10% w/v, pH 7.0) at 28°C for 1 week.

Maintenance procedures

Strains of the genus *Yaniella* were maintained on ISP5 agar slants containing 10% KCl (w/v) at 4°C and in glycerol suspensions (20% v/v) at −20°C. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of the genus *Yaniella* from other genera

Table 98 of the chapter on the genus *Kocuria* shows the differential phenotypic characteristics of the genus *Yaniella* and the phylogenetically related genera of the family *Micrococcaceae*. The genus *Yaniella* shares the peptidoglycan variation A4α Lys←Gly←Glu with the genera *Citricoccus* (Altenburger et al., 2002; Li et al., 2005b) and *Nesterenkonia* (Collins et al., 2002b; Li et al., 2005a; Stackebrandt et al., 1995), but differs from both genera in a remarkably lower range of DNA G+C values and from the genus *Citricoccus* additionally in the occurrence of completely unsaturated menaquinones.

Taxonomic comments

Recently, the genus name *Yania* was proved to be illegitimate because of the precedence of the genus name *Yania* in zoological descriptions and was replaced by the name *Yaniella* (Li et al., 2008b).

List of species of the genus *Yaniella*

1. **Yaniella halotolerans** (Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a) Li, Zhi and Euzéby 2008b, 526^{VP} (Illegitimate homotypic synonym: *Yania halotolerans* Li, Chen, Xu, Zhang, Schumann, Tang, Xu and Jiang 2004a, 530)

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. pres. part. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating, referring to the organism's ability to tolerate high salt concentrations.

In addition to the properties given in the genus description, this species has the following characteristics. Colonies reach maximum size (2 mm in diameter) after 1 week incubation at 28°C. They are yellow, circular, lubricious, and opaque. Almost all carbon sources tested are utilized, including glucose, galactose, arabinose, starch, cellobiose, lactose, mannose, mannitol, fructose, sucrose, maltose, and xylose, but acid is produced only from glucose, maltose, sucrose, and fructose. Positive for milk peptonization and urease, but negative for milk coagulation, nitrate reduction, gelatin liquefaction, growth on cellulose, and production of H_2S and melanin. Starch and Tweens 20, 40, and 80 are not hydrolyzed. Cells do not form indole; methyl red and Voges–Proskauer tests are negative. Temperature range for growth is 10–40°C, with an optimum temperature of 28–30°C. Growth pH is optimal at 7.0–8.0. Concentration ranges of NaCl, KCl, and $MgCl_2 \cdot 6H_2O$ for growth are 0–25, 0–20 and 0–15%, respectively. Menaquinones are MK-8, MK-7, and MK-9. Major cellular fatty acids are $C_{15:0}$ iso and $C_{15:0}$ anteiso.

Source: saline soil that was collected in Xinjiang Province, west China.

DNA G+C content (mol%): 53.5 (T_m).

Type strain: YIM 70085, CCTCC AA 001023, DSM 15476, JCM 13527.

Sequence accession no. (16S rRNA gene): AY228479.

2. **Yaniella flava** (Li, Schumann, Zhang, Xu, Chen, Xu, Stackebrandt and Jiang 2005c), Li, Zhi and Euzéby 2008b, 526^{VP} (Illegitimate homotypic synonym: *Yania flava* Li, Schumann, Zhang, Xu, Chen, Xu, Stackebrandt and Jiang 2005c, 1937)

fla′va. L. fem. adj. *flava* golden yellow, referring to the color of the colonies.

In addition to the properties given in the genus description, this species has the following characteristics. Colonies are light yellow, circular, lubricous, and opaque. Acid is produced from glucose, maltose, and fructose. It is negative for milk peptonization, milk coagulation, urease, and nitrate reduction, gelatin liquefaction, growth in cellulose, H_2S and melanin production. Some other physiological and biochemical characteristics are listed in Table 104. The cell-wall peptidoglycan type is A4α, L-Lys←Gly←L-Glu. The polar lipids contain diphosphatidylglycerol, phosphatidylglycerol, an unknown phospholipid, and an unknown glycolipid. The predominant menaquinones are MK-8 and MK-9. The major cellular fatty acid is $C_{15:0}$ anteiso.

Source: a saline soil collected from Qinghai Province, north-west China.

DNA G+C content (mol%): 57.9 (HPLC).

Type strain: YIM 70178, DSM 16377, JCM 13595, KCTC 19047.

Sequence accession no. (16S rRNA gene): AY684123.

Genus X. **Zhihengliuella** Zhang, Schumann, Yu, Liu, Zhang, Xu, Stackebrandt, Jiang and Li 2007, 1018[VP] emend. Tang, Wang, Chen, Lou, Cao, Xu, and Li 2009, 2029

Hans-Jürgen Busse

Zhi.heng.li.u.el′la. N.L. fem. dim. n. *Zhihengliuella* named after Zhi-Heng Liu (1940–), a Chinese microbiologist who devotes himself to the study of actinomycete taxonomy.

Gram-stain-positive, mesophilic and aerobic. Cells are **non-motile, non-spore-forming, short rods** (0.6–1.0 × 1.5–2.0 µm). Catalase-positive and oxidase-negative. The **peptidoglycan type is A4**, L-lys–L-ala–L-glu. The predominant **menaquinones** are **MK-9 and MK-10;** MK-8 occurs in smaller amounts. The **major fatty acids** are **$C_{15:0}$ anteiso and $C_{15:0}$ iso, or $C_{15:0}$ anteiso and $C_{17:0}$ anteiso**. The major **polar lipids** are **phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol**. **Diagnostic cell-wall sugars** are **tyvelose and mannose**.

DNA G+C content (mol%): 66.5–70.3 (HPLC).

Type species: **Zhihengliuella halotolerans** Zhang, Schumann, Yu, Liu, Zhang, Xu, Stackebrandt, Jiang and Li 2007, 1018[VP].

Further descriptive information

The genus *Zhihengliuella* consists of two species, *Zhihengliuella halotolerans* and *Zhihengliuella alba* which are sharing 97.5% 16S rRNA gene sequence similarity; differential characteristics are given in Table 106. Phylogenetically, the genus *Zhihengliuella* is placed in the family *Micrococcaceae* but the position within the family is not stable as indicated by different positions in different phylogenetic trees and low bootstrap support (Tang et al., 2009; Zhang et al., 2007). The type species of the genus *Zhihengliuella halotolerans* shares highest 16S rRNA gene sequence similarities with the type strains of certain *Micrococcus* and *Arthrobacter* species including *Arthrobacter oryzae* (96.4%), *Arthrobacter pascens* (96.2%), *Arthrobacter woluwensis* (96.1%), *Arthrobacter kerguelensis*, *Micrococcus antarcticus*, *Micrococcus luteus* (all 96.0%), *Arthrobacter psychrophenolicus*, *Arthrobacter arilaitensis*, *Arthrobacter mysorens* (all 95.9%), *Micrococcus lylae*, and *Arthrobacter globiformis* (95.7%). These data do not suggest close affiliation with either *Micrococcus* or *Arthrobacter*. Since no sequences of unnamed strains are deposited in gene banks with strains that share more than 97% 16S rRNA gene similarities, availability of other strains of this genus in institutional collections is not indicated. The fatty acid profile consists predominantly (>90%) of iso- and anteiso-branched acids which is similar to other representatives of the family *Micrococcaceae*. The uniqueness of *Zhihengliuella* species is indicated by the sugar tyvelose found with glucose in the cell wall. This characteristic has not been reported for any related taxa. The diagnostic diamino acid lysine supports affiliation of *Zhihengliuella halotolerans* with the *Micrococcaceae*, whereas the interpeptide bridge L-Ala–L-Glu is only reported as a characteristic of certain species of the *Arthrobacter nicotianae* group (*sensu* Keddie et al., 1986), including *Arthrobacter*

TABLE 106. Characteristics distinguishing between *Zhihengliuella halotolerans* and *Zhihengliuella alba*

Characteristic	*Z. halotolerans*	*Z. alba*
Pigmentation	Pale yellow[a]	White
NaCl range for growth (%, w/v)	0–25[a]	0–15
Optimal NaCl concentration (%, w/v)	10[a]	5
pH range for growth	6–10[a]	5–9
Optimum pH range	8–9[a]	6–8
Hydrolysis of:		
Starch	+	–
Tween 20	+	–
Utilization of (Biolog GP2):		
L-Arabinose, β-cyclodextrin, gentiobiose, maltotriose, melibiose, methyl β-D-galactoside, methyl β-D-glucoside, methyl α-D-mannoside, salicin, sedoheptulosan, D-sorbitol, stachyose, turanose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-D-ketoglutaric acid, D-malic acid, L-malic acid, pyruvic acid methyl ester, pyruvic acid, succinamic acid, D-alanine, L-alanyl glycine L-glutamic acid, 2,3-butanediol, inosine, uridine, thymidine-5′-monophosphate, uridine-5′-monophosphate, D-fructose 6-phosphate, α-D-glucose 1-phosphate, D-glucose 6-phosphate, α-DL-glycerol phosphate	+	–
L-Asparagine, L-serine, 2′-deoxyadenosine, *N*-acetyl-D-galactosamine, cellobiose, α-D-lactose	–	+
Enzyme activities (API ZYM):		
Alkaline phosphatase, lipase (C14)	+	–
Leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, β-glucosidase	–	+
Acid production from (API 50CHB):		
L-Arabinose, glycerol, D-adonitol, D-sorbitol, methyl β-D-xylopyranoside, inositol, arbutin, esculin, salicin, raffinose, turanose, glycogen, xylitol, gentiobiose, D-arabitol, potassium 5-ketogluconate	+	–
L-Xylose, D-glucose, sucrose	–	+
DNA G+C content (mol%)	66.5[a]	70.3

[a]Data for *Zhihengliuella halotolerans* are from Zhang et al. (2007). All other data are from Tang et al. (2009).

gangotriensis, *Arthrobacter kerguelensis*, *Arthrobacter psychrophenolicus*, and *Arthrobacter sulfureus*. The quinone system consisting predominantly of completely unsaturated menaquinones MK-9, MK-10, and small amounts of MK-8 is a characteristic similarly found in certain species of the *Arthrobacter nicotianae* group and in *Renibacterium*. Both the quinone system and interpeptide bridge might suggest a closer affiliation of *Zhihengliuella* with the *Arthrobacter nicotianae* group but this proposal is so far not supported by 16S rRNA based phylogeny.

Pathogenicity. No pathogenic potential was reported for any of the *Zhihengliuella* species, and neither the source of isolation (saline soil) nor NaCl preference (5–10%) suggest any pathogenic potential for humans.

Maintenance procedures

Cultures of *Zhihengliuella halotolerans* may be stored on marine agar (Difco 2216) slants at 4°C and as 20% (w/v) glycerol suspensions at −20°C. Cultures of *Zhihengliuella alba* may be stored on ISP 5 agar* slants containing 5% NaCl at 4°C and as 20% (w/v) glycerol suspensions at −20°C.

Differentiation of the genus *Zhihengliuella* from other genera

Zhihengliuella species may be differentiated chemotaxonomically from related genera based on the quinone system, peptidoglycan composition, cell-wall sugars, and with some restrictions, also fatty acid profile.

List of species of the genus *Zhihengliuella*

1. **Zhihengliuella halotolerans** Zhang, Schumann, Yu, Liu, Zhang, Xu, Stackebrandt, Jiang and Li 2007, 1018[VP]

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans* salt-tolerating, referring to the organism's ability to tolerate high salt concentrations.

The characteristics are as described for the genus with the following additional features. Pale-yellow colonies are circular, opaque, and approximately 1.0 mm in diameter after 24 h at 28°C. Optimum growth occurs at pH 8.0–9.0 and at 28–30°C with 10% NaCl. Negative for ornithine decarboxylase, urease, *N*-acetylglucosaminidase, β-galactosidase, α-glucosidase, gelatin liquefaction, methyl red test, Voges–Proskauer test, and nitrate reduction, but positive for arginine dihydrolase, lysine decarboxylase, lipase, β-glucosidase, α-galactosidase, ammonia production, starch, hydrolysis of Tween 20 and 80, and milk peptonization. Malonate is utilized and acid is produced from maltose, glucose, sucrose, L-arabinose, and trehalose. The cell wall contains glucose and tyvelose. Polar lipids include an unknown phospholipid and an unknown glycolipid. The menaquinones are MK-9, MK-10, and MK-8 (ratio, 5:2:1). The cellular fatty acid profile contains $C_{15:0}$ anteiso (63.9%), $C_{15:0}$ iso (15.0%), $C_{17:0}$ anteiso (8.5%), $C_{16:0}$ iso (7.1%), $C_{16:0}$ (2.5%), $C_{17:0}$ iso (1.0%), $C_{14:0}$ iso (0.8%), $C_{14:0}$ (0.8%), $C_{15:0}$ (0.2%), and $C_{15:1}$ anteiso (0.2%).

Source: saline soil sample collected from Qinghai province, north-west China.

DNA G+C content (mol%): 66.5 (HPLC).

Type strain: YIM 70185, DSM 17364, JCM 15629, KCTC 19085.

Sequence accession no. (16S rRNA gene): DQ372937.

2. **Zhihengliuella alba** Tang, Wang, Chen, Lou, Cao, Xu and Li 2009, 2029[VP]

al′ba. L. fem. adj. *alba* white, referring to the white color of colonies.

Cells are aerobic, Gram-stain-positive, short rods, 0.5–0.9 × 1.3–1.8 µm in size, non-motile, and without flagella. Colonies are circular, smooth, and white on modified ISP 5 medium.* Growth occurs in 0–15% (w/v) NaCl, with good growth at 5% (w/v) NaCl. Growth occurs at 4–45°C and pH 5.0–9.0, with optimum growth at 28–37°C and pH 6.0–8.0. Catalase-positive and oxidase-negative. Negative for milk peptonization, methyl red, and Voges–Proskauer tests, H_2S production, nitrate reduction, and hydrolysis of starch, urea, cellulose, casein, chitin and Tween 20. Positive for hydrolysis of esculin, gelatin, Tween 40, and Tween 80. Enzyme activities (API ZYM) are observed for esterase (C4), esterase lipase (C8), leucine arylamidase, valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, acid phosphatase, naphthol-AS-BI-phosphohydrolase, β-galactosidase, α-glucosidase and β-glucosidase. Negative for alkaline phosphatase, lipase (C14), α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Acid is produced (API 50CHB) from erythritol, D-ribose, DL-xylose, D-glucose, D-fructose, L-sorbose, L-rhamnose, D-mannitol, amygdalin, maltose, sucrose and starch, but not from glycerol, L-arabinose, D-arabinose, D-adonitol, methyl β-D-xylopyranoside, D-galactose, D-mannose, dulcitol, inositol, D-sorbitol, methyl α-D-mannopyranoside, methyl α-D-glucopyranoside, *N*-acetylglucosamine, turanose, arbutin, aesculin, cellobiose, salicin, D-lactose, melibiose, trehalose, inulin, melezitose, raffinose, glycogen, xylitol, gentiobiose, D-lyxose, D-tagatose, DL-fucose, DL-arabitol, potassium gluconate, potassium 2-ketogluconate, and potassium 5-ketogluconate. The following substrates are oxidized in the Biolog GP2 test: dextrin, mannan, Tweens 40 and 80, *N*-acetyl-D-galactosamine, D-arabitol, cellobiose, D-fructose, D-galactose, α-D-glucose, *myo*-inositol, α-D-lactose, maltose, D-mannitol, D-mannose, methyl α-D-glucoside, palatinose, D-psicose, raffinose, L-rhamnose, D-ribose, sucrose, D-tagatose, trehalose, xylitol, D-xylose, α-ketovaleric acid, succinic acid monomethyl ester, propionic acid, pyruvic acid, L-asparagine, L-serine, glycerol, 2′-deoxyadenosine, and thymidine. The following substrates are not oxidized: α-cyclodextrin, β-cyclodextrin, starch, inulin, *N*-acetyl-D-glucosamine, amygdalin, L-arabinose, arbutin, L-fucose, D-galacturonic acid, gentiobiose, D-gluconic acid, lactulose, melezitose, melibiose, methyl α-D-galactoside, methyl

*ISP 5 medium comprising (per 1 distilled water, final pH 7.5): 1 g L-asparagine, 10 g glycerol, 5 g yeast extract, 1 g K_2HPO_4, 5 g KNO_3, 100 g NaCl, and 15 g agar. NaCl is sterilized separately before being added to the medium.

β-D-galactoside, 3-methyl-D-glucose, methyl β-D-glucoside, methyl α-D-mannoside, salicin, sedoheptulosan, D-sorbitol, stachyose, turanose, acetic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, ρ-hydroxyphenylacetic acid, α-ketoglutaric acid, lactamide, D-lactic acid methyl ester, L-lactic acid, D-malic acid, L-malic acid, pyruvic acid methyl ester, pyruvic acid, succinamic acid, succinic acid, *N*-acetyl-L-glutamic acid, L-alaninamide, DL-alanine, L-alanyl glycine, L-glutamic acid, glycyl L-glutamic acid, L-pyroglutamic acid, putrescine, 2,3-butanediol, adenosine, inosine, uridine, adenosine-5′-monophosphate, thymidine-5′-monophosphate, uridine-5′-monophosphate, D-fructose 6-phosphate, α-D-glucose 1-phosphate, D-glucose 6-phosphate, and DL-α-glycerol phosphate. Peptidoglycan type is A4α, L-Lys–L-Ala–L-Glu. Major cell sugars contain tyvelose and mannose; minor amounts of glucose, rhamnose and galactose are also detected. Predominant menaquinones are MK-10 (64.0%) and MK-9 (32.7%); a minor amount of MK-8 (3.3%) is also detected. Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, an unknown phospholipid, and two unknown glycolipids. Major cellular fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso; minor amounts of $C_{14:0}$, $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{15:1}$ anteiso, $C_{16:0}$, $C_{16:0}$, $C_{17:0}$ iso, and $C_{18:0}$ are also detected.

Source: saline soil sample collected from Ganjiahu Suosuo Forest National Nature Reserve in Xinjiang province, northwest China.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: YIM 90734, KCTC 19375, DSM 21143.

Sequence accession no. (16S rRNA gene): EU847536.

Beu′ten.ber.gi.a.ce′a.e. N.L. fem. n. *Beutenbergia* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Beutenbergiaceae* the family of *Beutenbergia*.

Cells are irregular rods and cocci which occur singly, in pairs, or in small clusters. A rod–coccus growth cycle may be expressed. Gram-stain-positive. Endospores are not observed. **Nonmotile. Aerobic and facultatively anaerobic**. Colonies are circular, convex, and vary in color from white to yellow. Members of the family grow well on complex organic media and utilize a broad spectrum of carbon sources. Optimum growth between 28 and 37°C. Oxidase-positive or negative, **catalase-positive**. The characteristic diamino acids in the peptidoglycan are L-lysine or L-ornithine which correspond to the **peptidoglycan types A4α or A4β**, respectively. The major menaquinone is **MK-8(H_4)**. The pattern of polar lipids typically consists of diphosphatidylglycerol and (with the exception of *Serinibacter*) several unidentified phospholipids, and possibly phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine. The cellular fatty acid profiles are dominated by **iso- and anteiso-branched-chain acids and minor amounts of saturated straight-chain acids**. The family currently accommodates the genera *Beutenbergia*, *Salana*, *Serinibacter*, and *Miniimonas*. The pattern of 16S rRNA gene sequence signatures consists of nucleotides at positions 144:178 (C–G), 280 (U), 293:304 (G–U), 668:738 (A–U), 1003:1038 (G–U), 1027:1034 (U–A), and 1414:1486 (U–A). Members of the family were isolated from cave soil, river sediments, sea sand, and the intestinal tract of a fish.

DNA G+C content (mol%): 71–75.

Type genus: **Beutenbergia** Groth, Schumann, Schuetze, Augsten, Kramer and Stackebrandt 1999b, 1738[VP].

Taxonomic comments

The genus *Beutenbergia* has been established by Groth et al. in 1999 for two strains isolated from cave soil. Comparison of 16S rRNA gene sequences showed that the two strains shared a 100% sequence similarity between each other and that they were phylogenetically members of the order *Micrococcales*. However, the low sequence similarity values to members of other families together with the fact that *Beutenbergia cavernae* shared only 9–59% of signature nucleotides defining families within the *Micrococcales* indicated that these strains could not be affiliated to any described genus or family of this order. With the descriptions of the genera *Salana* (von Wintzingerode et al., 2001) and *Serinibacter* (Hamada et al., 2009), it became obvious that the relationship of these two genera is closer to *Beutenbergia* than to all previously described genera of the *Actinobacteria*. These findings supported the proposal of the new family *Beutenbergiaceae* (Zhi et al., 2009) containing the genera *Beutenbergia*, *Georgenia*, and *Salana*. Hamada et al. (2009) emended the family descriptions of the *Beutenbergiaceae* and the *Bogoriellaceae*. Hamada et al. (2009) defined the family *Bogoriellaceae* on the basis of the pattern of 16S rRNA gene sequence signatures, i.e. nucleotides at positions 144:178 (U–G), 293:304 (G–U), 479 (U), 602:636 (C–G), 668:738 (A–U), 1003:1038 (G–C), 1027:1034 (C–G), and 1409:1491 (C–G) and to include the genera *Bogoriella* (Groth et al., 1997a) and *Georgenia* (Altenburger et al., 2002; Li et al., 2007). The family *Beutenbergiaceae* comprised the genera *Beutenbergia*, *Salana*, and *Serinibacter* and was defined mainly on the basis of the pattern of 16S rRNA gene sequence signatures, i.e. nucleotides at positions 144:178 (C–G), 280 (U), 293:304 (G–U), 668:738 (A–U), 1003:1038 (G–U), 1027:1034 (U–A), and 1414:1486 (U–A) (Hamada et al., 2009). Recently the genus *Miniimonas* (Ue et al., 2011) was described containing the signature nucleotides of the family *Beutenbergiaceae*, and the family description was emended by Ue et al. (2011) to change the nucleotide pair at position 131:231 to A–G, not C–G per Zhi et al. (2009). Differential characteristics of the genera *Beutenbergia*, *Salana*, *Serinibacter*, and *Miniimonas* are indicated in Table 107. Patterns of selected 16S rRNA gene signature nucleotides are given in Table 108. The 16S rRNA gene sequence-based phylogenetic tree showing the positions of the members of the family *Beutenbergiaceae* is given in Figure 142.

TABLE 107. Differentiation of the genera *Beutenbergia*, *Miniimonas*, *Salana*, and *Serinibacter*[a,b]

Characteristic	*Beutenbergia*	*Miniimonas*	*Salana*	*Serinibacter*
Cell morphology	Irregular rods and cocci, rod–coccus cycle	Rods–coccoid	Short rods and cocci, club- like forms, rod–coccus cycle	Irregular, short rods
Relationship to oxygen	Aerobic to microaerobic	Aerobic and anaerobic	Aerobic and anaerobic	Aerobic and anaerobic
Oxidase	–	–	w	–
Cell-wall diamino acid	L-Lys	L-Orn	L-Orn	L-Lys
Peptidoglycan type	A4α	A4β	A4β	A4α
Predominant cellular fatty acids	$C_{15:0}$ iso, $C_{15:0}$ anteiso	$C_{15:0}$ anteiso, $C_{16:0}$	$C_{15:0}$ anteiso, $C_{14:0}$	$C_{15:0}$ anteiso, $C_{16:0}$
Polar lipids	DPG, PI, 3 PL	PG, DPG, PI, 1 PL	DPG, PG, PLs	PE, PG
DNA G+C content (mol%)	71	74	75	71

[a]Symbols: –, negative; w, weakly positive. Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PL, unidentified phospholipid.

[b]Data from Groth et al. (1999b), von Wintzingerode et al. (2001), Hamada et al. (2009), and Ue et al. (2011).

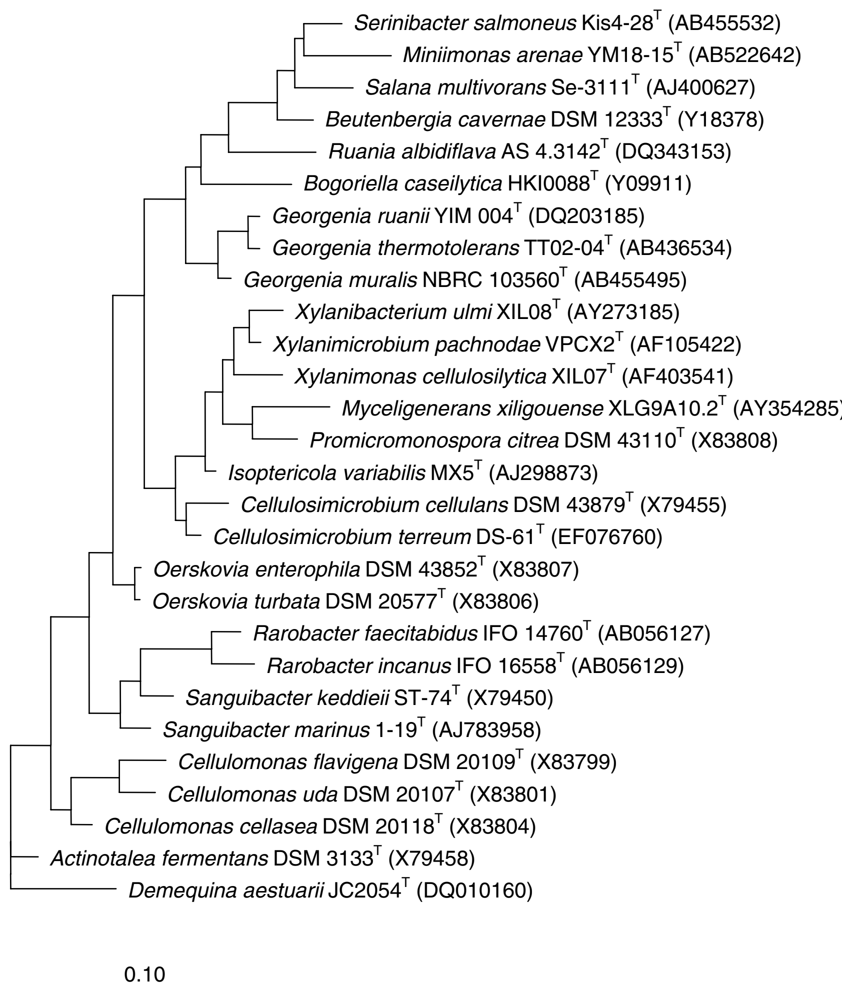

FIGURE 142. Phylogenetic analysis based on 16S rRNA gene sequences available from EMBL (accession numbers in parentheses). The phylogenetic tree was constructed using the ARB software package. Tree building was performed using the maximum-likelihood method with fastDNAml without filters. Bar = 0.10 nucleotide substitutions per nucleotide position.

Genus I. **Beutenbergia** Groth, Schumann, Schuetze, Augsten, Kramer and Stackebrandt 1999b, 1738[VP]

Ingrid Groth

Beu.ten.ber′gi.a. N.L. fem. n. *Beutenbergia* referring to Beutenberg, the geographical location of the institute in which the soil sample was studied.

Cells are irregular rods (0.5–0.8 × 1.0–3.1 μm) **and cocci** (0.7–1.0 μm). They occur singly, in pairs, short chains, or clusters and exhibit a **rod–coccus growth cycle (Figure 143 and Figure 144)**. Gram-stain-positive, not acid-fast. **Endospores are not formed. Nonmotile**. **Aerobic to microaerobic.** Colonies grown on rich (R) agar are smooth, circular, convex, opaque with entire margins and cream to bright yellow in color. Good growth on complex organic media at 28°C. NaCl in the culture medium may be tolerated up to 4%. **Oxidase-negative, catalase-positive**. The **peptidoglycan type is A4α** based on L-lysine. The **acyl type is acetyl**. Whole cell sugars are **glucose, mannose, and galactose**. The predominant menaquinone is **MK-8(H_4)**; MK-8(H_2), MK-8, and MK-9(H_4) occur in minor amounts. The polar lipids consist of **phosphatidylinositol, diphosphatidylglycerol, and unknown phospholipids. The cellular fatty acid profile** is dominated by the occurrence of **iso- and anteiso-branched-chain acids.** Mycolic acids are absent. Based on 16S rRNA gene sequence similarities, strains of *Beutenbergia* are closely related both to genera of the families *Beutenbergiaceae* (*Salana*, *Serinibacter* and *Miniimonas*) and *Bogoriellacea* (*Georgenia* and *Bogoriella*) and to the genera *Cellulosimicrobium* (*Promicromonosporaceae*), *Sanguibacter* (*Sanguibacteraceae*), and *Intrasporangium* (*Intrasporangiaceae*), and the genus *Ruania*. The 16S rRNA gene signature nucleotides that differentiate the genus from the other genera of the *Beutenbergiaceae* are listed in Table 108.

DNA G+C content (mol%): 71 (HPLC).

Type species: **Beutenbergia cavernae** Groth, Schumann, Schuetze, Augsten, Kramer and Stackebrandt 1999b, 1738[VP].

Further descriptive information

Currently the genus is represented by only one species *Beutenbergia cavernae* which includes two strains of the same origin. 16S rRNA gene sequence comparisons showed that the two strains share a 100% sequence similarity between one another and form a clade in the 16S rRNA gene tree of the suborder *Micrococcineae* (elevated to order *Micrococcales* in the taxonomic outline to the present volume) (Stackebrandt et al., 1997) with *Salana multivorans* (von Wintzingerode et al., 2001), *Serinibacter salmoneus* (Hamada et al., 2009) and *Miniimonas arenae* (Ue et al., 2011; Figure 142, chapter on *Beutenbergiaceae*). *Beutenbergia cavernae* shares a 16S rRNA gene sequence similarity of 97.1% with *Miniimonas arenae*, 96.5% with *Serinibacter salmoneus*, and 95.9% with *Salana multivorans*, and 94.6–95.3% with two species of *Georgenia* (Altenburger et al., 2002; Li et al., 2007), 94.0% with *Ruania albidiflava* (Gu et al., 2007), and 93.9% with *Bogoriella caseilytica* (Groth et al., 1997a). Interestingly, a high value of 96.0% 16S rRNA gene sequence similarity is also found

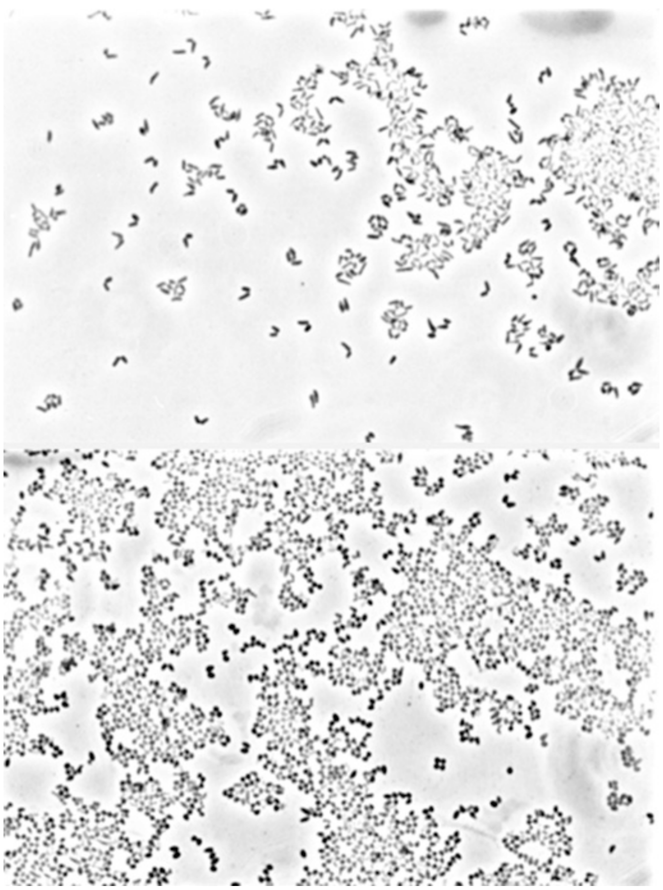

FIGURE 143. Micrographs of cells from *Beutenbergia cavernae* DSM 12333[T] grown at 28°C in liquid R medium for (top) 24 h or (bottom) 96 h. Bars = 10 μm.

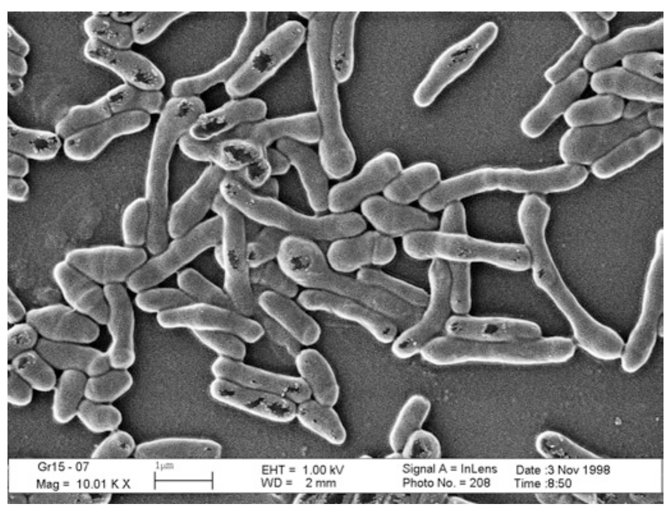

FIGURE 144. Scanning electron micrograph of cells from a 72-h-old culture of *Beutenbergia cavernae* DSM 12333[T] grown at 28°C on R agar. Bar = 1 μm.

between *Beutenbergia cavernae* and *Cellulosimicrobium cellulans* (Schumann et al., 2001). Furthermore *Beutenbergia cavernae* shares a relatively high level of 16S rRNA gene sequence similarity with *Sanguibacter keddieii* (94.1%; Fernández-Garayzábal et al., 1995) or *Intrasporangium calvum* (94.0%; Kalakoutskii et al., 1967). The 16S rRNA gene sequence of *Beutenbergia cavernae* possesses almost all of the signature nucleotides which are described to define members of the order *Micrococcales*. Only the A–A pair in position 722:723 is replaced by a G–G pair, which is also present in the strains of *Georgenia muralis* (Altenburger et al., 2002). The 16S rRNA gene signature nucleotides that define the genus *Beutenbergia* are listed in Table 108. The peptidoglycan of *Beutenbergia cavernae* contains Ala, Glu, and Lys in a molar ratio of 2.1:2.2:1.0. The interpeptide bridge consists of L-Lys–L-Glu which is in accordance with the peptidoglycan type A11.54 (DSMZ Catalogue of Strains, 1998, or http://www.dsmz.de), a variation of the peptidoglycan type A4α (Schleifer and Kandler, 1972).

Enrichment and isolation procedures

Beutenbergia cavernae grows readily in complex liquid or on solidified media, i.e. Bacto nutrient agar,* rich (R) medium† (Yamada and Komagata, 1972), Bacto tryptic soy broth,‡ and peptone-yeast extract-brain heart infusion medium** (PY-BHI, Yokota et al., 1993). The two strains of *Beutenbergia cavernae* were isolated from a cave on casein mineral medium†† (Altenburger et al., 1996) and on PY-BHI agar using a standard dilution plate procedure.

Maintenance procedures

Cultures of *Beutenbergia cavernae* can be maintained by serial transfers on the solidified complex media listed above. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Beutenbergia* from other genera

Beutenbergia can be distinguished from the other genera of the family *Beutenbergiaceae* by differences in the patterns of 16S rRNA gene signature nucleotides (Table 108), 16S rRNA gene sequence similarities ranging from 95.9–97.1%, and by a broad spectrum of phenotypic characteristics (Table 107). As all the members of the family *Beutenbergiaceae* are currently represented by only one species, the phylogenetic and phenotypic differences between the genera will become more obvious as further strains of the family become available. The closest phylogenetic neighbor of *Beutenbergia* within the *Beutenbergiaceae* is the genus *Miniimonas* which can be distinguished from *Beutenbergia* by the presence of L-ornithine as cell-wall diaminoacid (peptidoglycan type A4β), the composition of the polar lipids and a DNA G+C content of 74 mol%. The genus *Serinibacter* shares with *Beutenbergia* the peptidoglycan type A4α, but is characterized by the presence of serine and the absence of L-alanine in the peptidoglycan and by differences in the pattern of polar lipids. The genus *Salana* can be distinguished from *Beutenbergia* by the peptidoglycan type A4β. Further differentiating characteristics between these two genera are quantitative differences in the contents of diagnostic cellular fatty acids, the absence of phosphatidylinositol in *Salana*, and differences in numerous physiological properties (Groth et al., 1999b; von Wintzingerode et al., 2001). *Beutenbergia cavernae* shares with the closely related *Georgenia muralis* the peptidoglycan type A11.54 with the interpeptide bridge L-Lys–L-Glu (Altenburger et al., 2002), which is not present in *Georgenia ruanii* (Li et al., 2007). In the one currently available strain of this species, a further peptidoglycan type (A11.35) with the interpeptide bridge L-Lys–L-Ala–L-Glu is found. Differences in the patterns of polar lipids, the fatty acid profiles, and a broad spectrum of physiological markers equally contribute to distinguish *Beutenbergia* from *Georgenia*. The rare peptidoglycan type A11.54, present in *Beutenbergia cavernae*, *Serinibacter salmoneus*, and *Georgenia muralis*, corresponds to that found in *Arthrobacter sulfureus* (Stackebrandt et al., 1983), a member of the family *Micrococcaceae* (Stackebrandt et al., 1997). Although the strains of *Beutenbergia cavernae* and *Arthrobacter sulfureus* are morphologically similar, they can be readily distinguished from one another by their low level of phylogenetic relationship and differences in the DNA G+C content, menaquinone type, pattern of polar lipids, and fatty acid profiles. The composition of the interpeptide bridge also serves to distinguish *Beutenbergia* from *Bogoriella* and *Ruania*. *Bogoriella* has an interpeptide bridge consisting of L-Lys–L-Ala–L-Ala–L-Glu, and that of *Ruania* consists of L-Lys–Gly–L-Glu–L-Glu. Further differences in phenotypic characteristics underline the phylogenetic distinctiveness between *Beutenbergia* and these two genera (Groth et al., 1997a; Gu et al., 2007). The genus *Demetria* (Groth et al., 1997b), which is also characterized by the presence of the peptidoglycan type A4α in combination with the menaquinone type MK-8(H_4), shares with *Beutenbergia* a 16S rRNA gene sequence similarity of only 91.4%. Numerous phenotypic characteristics including the composition of the interpeptide bridge of the peptidoglycan, pattern of polar lipids, fatty acid profile, and morphological and physiological properties clearly separate *Demetria* from *Beutenbergia*. The phylogenetically close genera *Cellulosimicrobium*, *Sanguibacter*, and *Intrasporangium* show the following phenotypic characteristics that distinguish them from *Beutenbergia*. Young cultures of *Cellulosimicrobium cellulans* form a primary mycelium that fragments later into irregular curved or club shaped rods. The peptidoglycan type is A4α with a D-Ser–D-Asp interpeptide bridge, and the major menaquinone is MK-9(H_4). Cells of *Sanguibacter* are typically facultative anaerobic, motile short rods. The peptidoglycan type A4α is based on L-Lys–L-Ser–D-Glu.

*Bacto nutrient agar consists of (g/l): Bacto beef extract, 3.0; Bacto peptone, 5.0, and Bacto agar, 15.0 (all from Difco); pH 6.8.

†Rich (R) medium consists of (g/l): Bacto peptone (Difco), 10.0; yeast extract (Difco), 5.0; Casamino acids (Difco), 5.0; beef extract (Difco), 2.0; malt extract (Difco), 5.0; glycerol, 2.0; $MgSO_4 \cdot 7H_2O$, 1.0; Tween 80, 0.05, and agar, 20.0; pH 7.2.

‡Bacto tryptic soy broth consists of (g/l): Bacto tryptone, 17.0; Bacto soytone, 3.0; glucose, 2.5; NaCl, 5.0; K_2HPO_4, 2.5 (all from Difco); pH 7.3.

**Peptone-yeast extract-brain heart infusion medium consists of (g/l): peptone, 10.0; yeast extract, 2.0; Bacto brain heart infusion (Difco), 2.0; NaCl, 2.0, and glucose, 2.0; pH 7.0.

††Casein mineral medium consists of (g/l): K_2HPO_4, 0.6; $Na_2HPO_4 \cdot 2H_2O$, 0.5; $MgSO_4 \cdot 7H_2O$, 0.05; $MgCl_2 \cdot 7H_2O$, 0.1; KNO_3, 0.2; $FeCl_3 \cdot 6H_2O$, 0.01; casein, 0.8, and yeast extract 0.4; pH 7.0.

$MK\text{-}9(H_4)$ is the predominant menaquinone. *Intrasporangium* is characterized by the formation of a branching mycelium, a peptidoglycan based on LL-A_2pm-Gly_3 (type A3γ), MK-8 as major menaquinone, and a DNA G+C content of 68 mol%.

Taxonomic comments

The genus *Beutenbergia* was established by Groth et al. (1999) for two strains isolated from cave soil. Comparison of 16S rRNA gene sequences showed that the two strains were phylogenetically members of the suborder *Micrococcineae*. However, the low sequence similarity values to members of other families together with the fact that *Beutenbergia cavernae* shared only 9–59% of the signature nucleotides that phylogenetically define families within the *Micrococcineae* indicated that these strains could not be affiliated to any described genus or family of this suborder (elevated to order *Micrococcales* in the taxonomic outline to the present volume). With the descriptions of the genera *Salana* (von Wintzingerode et al., 2001) and *Georgenia* (Altenburger et al., 2002), it became obvious that these two genera are more closely related to *Beutenbergia* than to previously described genera of the actinobacteria. These findings supported an affiliation of the genera *Beutenbergia*, *Salana*, and *Georgenia* to the tentative family "*Beutenbergiaceae*" (Garrity et al., 2007). However, when the 16S rRNA gene sequence of *Ruania* (Gu et al., 2007) was added to the database of the actinobacteria, it was expected from the correspondence in the 16S rRNA gene signature nucleotides that the genera *Beutenbergia*, *Bogoriella*, *Georgenia*, *Ruania*, and *Salana* could be affiliated to a common family. However, the update of the structure and definition (based on 16S rRNA gene sequence) of the higher ranks of the class *Actinobacteria* supported the proposal of the new family *Beutenbergiaceae* (Zhi et al., 2009) comprising the genera *Beutenbergia*, *Georgenia*, and *Salana*. Hamada et al. (2009) emended the descriptions of the families *Beutenbergiaceae* and *Bogoriellaceae*. Based on their phylogenetic studies, the family *Beutenbergiaceae* accommodates the genera *Beutenbergia*, *Salana*, and *Serinibacter*, and the genus *Georgenia* is placed into the family *Bogoriellaceae*. Ue et al. (2011) confirmed the results of Hamada et al. (2009) and added the genus *Miniimonas* to the family *Beutenbergiaceae*.

List of species of the genus *Beutenbergia*

1. **Beutenbergia cavernae** Groth, Schumann, Schuetze, Augsten, Kramer and Stackebrandt 1999b, 1738[VP]

ca.ver′na.e. L. n. *caverna* cave; L. gen. n. *cavernae* of a cave, referring to the habitat of the organism.

The description is the same as given for the genus. In addition, the organism displays the following phenotypic characteristics. Colonies grown on rich (R) agar vary in size from 0.7 to 1.8 mm. Young cultures are composed almost entirely of irregular rods arranged in palisades, clusters or pairs at an angle to give V-forms. In stationary phase cultures, coccoid cells dominate. Optimum temperature for growth is 28°C. Growth is reduced at 37°C and does not occur at 42°C and in the presence of 6% NaCl. Acids are produced from L-arabinose, D-cellobiose, dextrin, D-fructose, D-galactose, D-glucose, glycerol, inulin, maltose, D-mannose, D-raffinose, L-rhamnose, D-ribose, salicin, starch, sucrose, trehalose, and D-xylose. No acid production from D-glucitol, lactose, and D-mannitol. Acetate, aconitate, benzoate, citrate, formate, malate, succinate, and DL-tartrate are not utilized. Nitrate is reduced to nitrite, H_2S is produced, but not indole. Methyl red and Voges–Proskauer reactions are negative. Casein, esculin, gelatin, and potato starch are decomposed; but not adenine, hippurate, hypoxanthine, xanthine, Tween 80, tyrosine, and urea. Reactions of the API ZYM enzyme assay (bioMerieux) are positive for alkaline phosphatase, esterase (C 4), esterase lipase (C 8), leucine arylamidase, cystine arylamidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase, but negative for lipase (C 14), valine arylamidase, trypsin, chymotrypsin, β-glucuronidase, and β-glucosidase. Cells are susceptible to the following antibiotics (μg/disc): ampicillin (10), chloramphenicol (30), erythromycin (15), neomycin (30), oxytetracycline (30), penicillin G (2 IU/disc), polymyxin B (weakly, 300 IU/disc), rifampin (2), but not susceptible to ciprofloxacin (5), gentamicin (10), kanamycin (30), lincomycin (2), nitrofuran (300), oxacillin (5), streptomycin (10), and sulfonamide (300). The predominant cellular fatty acids are $C_{15:0}$ iso, $C_{15:0}$ anteiso, and $C_{16:0}$.

DNA G+C content (mol%): 71 (HPLC).

Type strain: HKI 0122, DSM 12333, ATCC BAA-8, CCUG 43141, CIP 106362, IFO (now NBRC) 16432, JCM 11478.

Sequence accession no. (16S rRNA gene): Y18378.

Genus II. **Miniimonas** Ue, Matsuo, Kasai and Yokota 2011, 125[VP]

Peter Kämpfer

Mi.ni.i.mo′nas. L.adj. *minius* cinnabar-red, vermilion; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Miniimonas* vermilion monad, referring to the cell mass color.

Cells are irregular rods 0.6 × 3.1 μm) **and cocci** (1.0–1.7 μm). Gram-stain-positive, not acid-fast. **Endospores are not formed. Nonmotile**. **Facultatively** an**aerobic.** Good growth on complex organic media at 28–30°C. NaCl in the culture medium may be tolerated up to 5%. **Oxidase-negative, catalase-positive**. The **peptidoglycan type is A4β** based on L-ornithine. The **acyl type is acetyl**. Whole cell sugars are **glucose, xylose, and ribose**. The predominant menaquinone is **$MK\text{-}8(H_4)$**. The

polar lipids consist of **phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and one unknown phospholipid. The cellular fatty acid profile** is dominated by the occurrence of **iso- and anteiso-branched-chain acids.** Mycolic acids are absent. Based on 16S rRNA gene sequence similarities, the genus is closely related the other genera of the family *Beutenbergiaceae* (96.3–97.3%).

DNA G+C content (mol%): 74.2 (HPLC).

Type species: **Miniimonas arenae** Ue, Matsuo, Kasai and Yokota 2011, 125[VP].

Further descriptive information

Currently the genus is represented by the only species *Miniimonas arenae* which accommodates only one strain. Comparison of 16S rRNA gene sequences showed that the type strain of *Miniimonas arenae* shares similarity with the type strains of *Beutenbergia cavernae* (96.3%), *Serinibacter salmoneus* (95.1%), and *Salana multivorans* (96.1%). The peptidoglycan of *Miniimonas arenae* contains Ala, Ser, Glu, and Orn in a molar ratio of 0.4:0.5:1.0:0.4. The interpeptide bridge consists of L-Orn–L-Glu which is in accordance with the peptidoglycan type A4β (Schleifer and Kandler, 1972).

Enrichment and isolation procedures

Miniimonas arenae grows readily in complex liquid or on solidified media, i.e. Bacto nutrient agar (Difco, g/l: Bacto beef extract, 3.0; Bacto peptone, 5.0, and Bacto agar, 15.0; pH 6.8), tryptone soy agar (Oxoid), H medium (Ue et al., 2011), and IL8 medium [(g/l): lactose 10 g, polypeptone 15 g, yeast extract 15 g, NaCl 10 g, and agar 15 g] at 28–30°C. The type strain of *Miniimonas arenae* was isolated from sea sand collected from Teguma fishing harbor in Nagasaki Perfecture (Japan) on H medium (Ue et al., 2011).

Maintenance procedures

Cultures of *Miniimonas arenae* can be maintained by serial transfers on the solidified complex media listed above. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (–140°C).

Differentiation of the genus *Miniimonas* from other genera

Miniimonas can be distinguished from the other genera of the family *Beutenbergiaceae* by differences in the family specific signature nucleotides. The pattern of 16S rRNA signatures consists of nucleotides at positions 140:223 (G–C), 589:128 650 (U–A), 610 (U), 612:628 (C–G), 616:624 (G–C), 839:847 (C–A) and 863 (A) (Ue et al., 2011), which is different from the other genera of the family *Beutenbergiaceae*. The 16S rRNA gene sequence similarity to the type strains of the genera *Beutenbergia*, *Salana*, and *Serinibacter* is 95.1–96.3%, and some phenotypic characteristics (Table 107) are characteristic for the genus. As all the members of the family *Beutenbergiaceae* are currently represented by only one or two species (Groth et al., 1999b; Hamada et al., 2009; von Wintzingerode et al., 2001), the phylogenetic and phenotypic differences between the genera will become more obvious when other strains of the family become available. The closest phylogenetic neighbor of *Miniimonas* within the *Beutenbergiaceae* is the genus *Serinibacter* (Figure 142, chapter *Beutenbergiaceae*).

List of species of the genus *Miniimonas*

1. **Miniimonas arenae** Ue, Matsuo, Kasai and Yokota 2011, 125[VP]

a.re′na.e. L.gen. n. *arenae* of sand, isolated from sea sand, referring to the source of isolation of the organism.

The description is the same as given for the genus. In addition the organism displays the following phenotypic characteristics. Cells sizes in rods vary from 0.6–3.7 µm in length. The diameters of the cocci are 1.0–1.7 µm. Growth occurs at 25–30°C and a wide pH range (5–11) and optimum (7–7.5). Cells grow in absence of NaCl but tolerate up to 5% NaCl (w/v). When grown aerobically for 7 d on LB agar or IL8 medium, a vermilion cell mass is formed. The organism does not form spores. Cells form circular and smooth colonies of 1–4 mm diameter. Nitrate is reduced to nitrite. H_2S is not produced. Hydrolysis of starch is negative. Based on API ZYM tests, cells are positive for esterase lipase (C8), leucine arylamidase, naphthol AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, α-glucosidase, and β-glucosidase but negative for alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase. Cells are weakly positive for esterase (C4) and acid phosphatase. Utilizes the following substrates a sole carbon sources: L-arabinose, D-mannose, D-xylose, D-glucose, D-fructose, L-rhamnose, D-maltose monohydrate, glucose, but cannot utilize D-mannitol. Anaerobic formation of acid from API 20A is positive for glucose, sucrose, maltose, D-xylose, L-arabinose, D-mannose, D-raffinose, L-rhamnose, and D-trehalose, weakly positive for D-cellobiose and negative for D-mannitol, lactose, salicin, glycerol, D-melezitose, and D-sorbitol. Based on API 20A tests, cells are anaerobically positive for the hydrolysis of esculin but negative for the hydrolysis of gelatin, the production of indole, arginine dihydrolase, and urease. The peptidoglycan type, polar lipids, fatty acid pattern, and major menaquinone are as described for the genus. The predominant cellular fatty acids (for the type strain in %) are $C_{15:0}$ anteiso (46.7) and $C_{16:0}$ (23.2), and minor fatty acids are $C_{17:0}$ anteiso (9.4), $C_{14:0}$ (5.4), $C_{16:0}$ iso (3.8), $C_{15:0}$ iso (3.4 %), $C_{14:0}$ iso (2.8), $C_{15:0}$ (2.3), and $C_{17:0}$ iso (1.5).

Source: sea sand from Teguma fishing harbor in Nagasaki Prefecture (Japan).

DNA G+C content (mol%): 74.2 (HPLC).

Type strain: YM18-15, NBRC 106267, KCTC 19750, MBIC 08348.

Sequence accession no. (16S rRNA gene): AB522642.

Genus III. **Salana** von Wintzingerode, Göbel, Siddiqui, Rösick, Schumann, Frühling, Rohde, Pukall and Stackebrandt 2001, 1659[VP]

Erko Stackebrandt

Sa.la′na. N.L. fem. n. *Salana* referring to the German river Saale, the source of the bioreactor culture.

Irregular rods and cocci, sometimes club-like forms (Figure 145). Gram-stain-positive. Facultatively anaerobic bacteria. **Anaerobically reduces selenate to elemental selenium.** A variety of organic electron donors may be utilized. The peptidoglycan is of the A4β type with an L-Orn ← L-Glu interpeptide bridge and an L-Ser residue at position 1 of the peptide subunit. The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and several unidentified phospholipids in minor amounts. The fatty acid pattern is of the iso and anteiso branched and straight chain saturated type. The major menaquinone is MK-8(H_4).

DNA G+C content (mol%): 75.

Type species: **Salana multivorans** von Wintzingerode, Göbel, Siddiqui, Rösick, Schumann, Frühling, Rohde, Pukall and Stackebrandt 2001, 1659[VP].

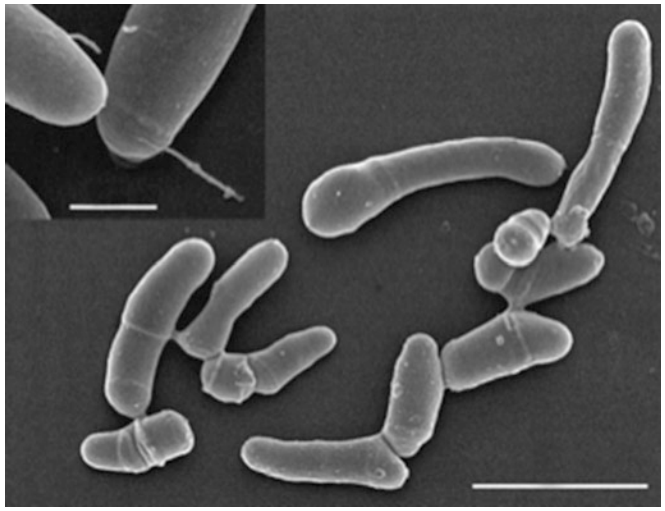

FIGURE 145. Scanning electron micrograph of cells of *Salana multivorans* Se-3111[T]. (main) Rod-shaped, coccoid and club-like cell morphotypes of strain Se-3111[T] (bar = 2 μm). (inset) Stalk-like elements located at the cell pole (bar = 0.2 μm).

Further descriptive information

The type strain DSM 13521[T] and two additional strains were characterized and found identical in all tests performed. Only the type strain was maintained in public collections. Strains were able to grow under aerobic and anaerobic conditions. Acidification of growth medium occurred in the presence of a large range of sugars and carbohydrates and the acidification by *Salana multivorans* was more pronounced than that by its phylogenetic neighbor, *Beutenbergia cavernae* (Groth et al., 1999b). API ZYM reactions were as follows: positive for alkaline phosphatase, esterase (C_4), esterase lipase (C_8), leucine arylamidase, cystine arylamidase, phosphatase acid, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-glucosidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, valine arylamidase; negative for trypsin, chymotrypsin, α-fucosidase, and β-glucuronidase. Lipase (C_{14}) weak. Acid was formed under aerobic conditions (according to API 50CH) from glycerol, D-arabinose, L-arabinose, ribose, D-xylose, methyl β-D-xyloside, methyl α-D-mannoside, amygdalin, arbutin, salicin, cellobiose, lactose, inulin, melezitose, starch, glycogen, xylitol, gentobiose, galactose, D-glucose, D-fructose, D-mannose, maltose, melibiose, sucrose, trehalose, D-raffinose, D-turanose, and D-lyxose. Negative acid formation from erythritol, L-xylose, adonitol, L-sorbose, rhamnose, dulcitol, inositol, mannitol, sorbitol, α-methyl-D-glucoside, *N*-acetylglucosamine, D-tagatose, D-fucose, L-fucose, D-arabitol, L-arabitol, gluconate, 2-keto-gluconate, and 5-keto-gluconate. Anaerobically acid was produced from glucose, mannitol, lactose, sucrose, maltose, xylose, salicin, arabinose, glycerol, cellobiose, mannose, melezitose, raffinose, sorbitol, rhamnose, and trehalose. All strains formed insoluble, elemental selenium when grown anaerobically in selenate containing medium (3.9×10^{-6}–2.8×10^{-5} mol/l). Cells formed slightly red colored colonies (diameter, 0.3–0.6 mm) when grown under anaerobic conditions for 14 d on selenate containing medium. When grown aerobically for 6 d on LB or Columbia blood agar, strains form yellow or white-gray colonies of 1.0 or 2.0 mm diameter. Stalk-like elements of up to 300 nm were visible at the poles of some cells (Figure 145, inset). The peptidoglycan contained Ala, Ser, Orn, and Glu in a molar ratio of 0.6:0.9:1.0:1.5. Detailed analysis (von Wintzingerode et al., 2001) indicated that *Salana multivorans* strains were characterized by novel peptidoglycan structure with an L-Orn ← L-Glu interpeptide bridge and an L-Ser residue at position 1 of the peptide subunit.

Enrichment and isolation procedures

Using culture conditions favoring enrichment of anaerobic, selenate respiring organisms, three strains (DSM 13521[T], Se-13111, and Se-1311) were isolated (von Wintzingerode et al., 1999). Only the type strain has been maintained in public collections. Samples were taken from a fluidized bed reactor (FBR) inoculated with an anaerobic, trichlorobenzene-dechlorinating consortium enriched from sediment of the river Saale near Jena, Germany (Selent, 1999). Within the FBR the dechlorinating consortium was immobilized on polyurethane foam cubes. For enrichment of anaerobic, selenate-reducing bacteria, foam cubes were removed from the bioreactor by a sterile forceps and transferred to reduced RAMM-medium (Shelton and Tiedje, 1984). After 7 d of incubation at 30°C under anaerobic conditions (GasPak anaerobic jars, Anaerogen), enrichment cultures were set up by transferring one foam cube each to Erlenmeyer flasks containing 50 ml of Se-medium (Macy et al., 1989): 2.2 g/l NaCl, 0.3 g/l KCl, 0.3 g/l NH_4Cl, 0.2 g/l KH_2PO_4, 0.15 g/l $CaCl_2{\cdot}2\,H_2O$, 0.4 g/l $MgCl_2{\cdot}6\,H_2O$, 0.6 g/l $NaHCO_3$, 3.78 g/l Na_2SeO_4, 3.78 g/l potassium acetate, 10 ml/l trace metal solution SL8, 10 ml/l vitamin solution, 800 μl/l methanol. After 5 d of anaerobic incubation in anaerobic jars (CO_2, N_2, and H_2 atmosphere), a red precipitate was visible and served as an inoculum for subcultures in modified Se-medium (1–4 g/l yeast extract, 1.2 g/l NaCl, 0.3 g/l Na_2SO_4, and 2.02 g/l KNO_3).

Pure cultures were obtained by repeated streaking on agar plates containing the above medium.

Maintenance procedures

After isolation cells were stored at −70°C in liquid growth medium supplemented with 30–50% (v/v) glycerol. Long-term preservation in liquid nitrogen.

Differentiation of the genus *Salana* from other genera

16S rRNA gene sequence analysis reveals the moderate relationship of *Salana multivorans* and *Beutenbergia cavernae* (95% similarity), suborder *Micrococcineae* (elevated to order *Micrococcales* in the present volume), class *Actinobacteria* (Stackebrandt et al., 1997), while relationships with the other members of the order were slightly lower (90% and 93%). The distance between branching points of the *Salana/Beutenbergia* lineage is statistically insignificant in distance matrix (De Soete, 1983; Figure 146) and maximum-likelihood (Felsenstein, 1993; not shown) 16S rDNA gene dendrograms. In the present volume, *Salana* is classified in the family *Beutenbergiaceae*, along with the genera *Beutenbergia*, *Serinibacter*, and *Miniimonas*. Physiological differences between *Salana multivorans* and *Beutenbergia cavernae* are shown in Table 109. Few morphological and chemotaxonomic characteristics differentiate *Salana multivorans* DSM 13521[T] from species of *Beutenbergia*, *Ruania*, *Georgenia*, *Bogoriella*, *Ornithinococcus*, and *Ornithinomicrobium*. These include mainly the composition, type, and variant of the peptidoglycan (Table 110). *Salana multivorans* and *Beutenbergia cavernae* also differ in the amino acid at position 1 of the peptide side chain (L-Ser and L-Ala, respectively). The latter two taxa also contain ornithine (A4β) in their murein and isoprenoid quinones of the MK-8(H_4) type.

List of species of the genus *Salana*

1. **Salana multivorans** von Wintzingerode, Göbel, Siddiqui, Rösick, Schumann, Frühling, Rohde, Pukall and Stackebrandt 2001, 1659[VP]

mul.ti.vo′rans. L. adj. *multus* many, numerous; L. v. *vorare* to devour, swallow; N.L. part. adj. *multivorans* devouring many, referring to the utilization of numerous kinds of substrates.

Rod-shaped to circular, sometimes club-like cells (0.4–0.7 μm in width, 1.2–3.1 μm in length). Electron microscopy showed the presence of polar stalk-like elements of up to 300 nm in length in some cells. Gram-stain-positive, nonmotile. Growth with formation of acid occurs under both aerobic and anaerobic conditions (API 20A and API 50CH substrate panels). Gelatin and esculin not hydrolyzed. Indole not formed, urease-negative. Catalase and oxidase reactions weak. Under anaerobic conditions, cells reduce selenate to elemental selenium. Amino-functional lipids and glycolipids are not found. The cellular fatty acid profile contains: 23.0%

tetradecanoic acid, 1.0% pentadecanoic acid, 17.0% hexadecanoic acid, 2.9% 12-methyl tridecanoic acid, 2.3% 14-methyl pentadecanoic acid, 50.4% 12-methyl-tetradecanoic acid, and 1.5% 14-methyl hexadecanoic acid. The major menaquinone is MK-8(H_4). MK-6(H_4), MK-7(H_4), and MK-8(H_2) occur as minor components. Some metabolic properties are described in *Further descriptive information*, above, and in Table 109.

Source: an anaerobic, dechlorinating bioreactor culture enriched from sediment of the German river Saale.

DNA G+C content (mol%): 75 (HPLC).

Type strain: Se-3111, DSM 13521, NRRL B-24118, JCM 13524.

Sequence (EMBL) accession no. (16S rRNA gene): AJ400627.

Genus IV. **Serinibacter** Hamada, Iino, Tamura, Iwami, Harayama and Suzuki 2009, 2812^{VP}

Peter Kämpfer

Se.ri.ni.bac′ter. N.L. n. *serinum* serine; N.L. masc n. *bacter* rod; N.L. masc. n. *Serinibacter* a rod with serine in the cell wall.

Cells are irregular rods (0.5 × 1.0–2.0 µm). Gram-stain-positive, not acid-fast. **Endospores are not formed. Nonmotile. Aerobic to anaerobic.** Good growth on complex organic media at 28–30°C. NaCl in the culture medium may be tolerated up to 10%. **Oxidase-negative, catalase-positive**. The **peptidoglycan type is A4α** with an L-Ser residue at position 1 of the peptide subunit. The **acyl type is acetyl**. The major cell wall sugar is **galactose**. The predominant menaquinone is **MK-8(H_4)**. The major polar lipids consist of **phosphatidylethanolamine and phosphatidylglycerol. The cellular fatty acid profile** is dominated by the occurrence of **iso- and anteiso-branched-chain acids.** Mycolic acids are absent. Based on 16S rRNA gene sequence similarities, the genus is closely related to other genera of the family *Beutenbergiaceae* (95.1–96.3%).

DNA G+C content (mol%): 70.7 (HPLC).

Type species: **Serinibacter salmoneus** Hamada, Iino, Tamura, Iwami, Harayama and Suzuki. 2009, 2812^{VP}.

Further descriptive information

Currently the genus is represented by the only species *Serinibacter salmoneus* which accommodates only one strain. Comparison of 16S rRNA gene sequences showed that the type strain of *Serinibacter salmoneus* strains shares similarity with the type strains of *Beutenbergia cavernae* (96.3%), *Miniimonas arenae* (95.1%), and *Salana multivorans* (96.1%). Patterns of selected 16S rRNA nucleotide signatures are given in Table 108. The peptidoglycan of *Serinibacter salmoneus* contains Ala, Glu, Lys, and Ser in a molar ratio of 1.0:2.1:0.9:1.0. The enantiomeric analysis of the peptidoglycan amino acids revealed the presence of D-Ala, D-Glu, L-Glu, L-Ser, and L-Lys; however, L-Ala was absent. These data indicated that the cell-wall peptidoglycan of strain Kis4-28^T was of the A4α type (Schleifer and Kandler, 1972), with lysine as the diagnostic cell-wall diamino acid, an interpeptide bridge of the peptidoglycan comprising L-Lys–L-Glu, and an L-Ser residue at position 1 of the peptide subunit (Hamada et al., 2009). The major cellular fatty acids of the type strain of *Serinibacter salmoneus* were $C_{15:0}$ anteiso (45.7), $C_{16:0}$ (24.4%), $C_{16:0}$ iso (11.5%), $C_{17:0}$ anteiso (10.5%), and minor fatty acids including $C_{14:0}$ (4.1%) and $C_{14:0}$ iso (3.8%). Beside galactose, which was the major cell-wall sugar, mannose, ribose, and xylose were detected as minor components (Hamada et al., 2009).

Enrichment and isolation procedures

Serinibacter salmoneus grows readily in complex liquid or on solidified media, i.e. Bacto nutrient agar (Difco, g/l: Bacto beef extract, 3.0; Bacto peptone, 5.0 and Bacto agar, 15.0; pH 6.8) and tryptone soy agar (Oxoid). The type strain of *Serinibacter salmoneus* was isolated from Japanese sillago (*Sillago japonica*), a fish collected from Kyonan beach on the coast of Tokyo Bay, Japan (Hamada et al., 2009). The sillago was dissected, and an intestinal tract sample of approximately 1 g was used for the isolation of bacteria. The procedure employed for bacterial isolation was as described by Iino et al. (2007). NBRC medium 802 containing 1.0% Polypeptone (Wako), 0.2% yeast extract (Difco), 0.1% $MgSO_4 \cdot 7H_2O$, and 1.5% agar (if required) was used for general laboratory cultivation (Hamada et al., 2009).

Maintenance procedures

Cultures of *Miniimonas arenae* can be maintained by serial transfers on the solidified complex media listed above. Growth on agar slants in screw-capped tubes can be kept at 4°C for about 2–4 weeks. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Serinibacter* from other genera

Serinibacter can be distinguished from the other genera of the family *Beutenbergiaceae* by differences in the family specific signature nucleotides (Table 108). A detailed phylogenetic analysis performed on the basis of the 16S rRNA gene sequence revealed that *Serinibacter salmoneus* formed a separate lineage with the type strains of *Salana multivorans*, *Beutenbergia cavernae*, and *Miniimonas arenae* (Figure 142). The amino acid composition of the peptidoglycan of *Serinibacter* was different from that of the genera *Salana*, *Beutenbergia*, and *Miniimonas*. The peptidoglycan of the isolate was of the A4α type, with L-Lys as the diagnostic cell-wall diamino acid. In contrast, the peptidoglycan of the genus *Salana* is reported to be of the A4β type, with L-ornithine as the diagnostic diamino acid (von Wintzingerode et al., 2001). The peptidoglycan of the genus *Miniimonas* is also reported to be of the A4β type but contained L-ornithine as the diagnostic diamino acid (Ue et al., 2011). In addition, the polar lipids are significantly different. Although the peptidoglycan type in species of the genus *Beutenbergia* is also A4α (Groth et al., 1999b), *Serinibacter* is different from this genus in that it contained L-Ser at position 1 of the peptide subunit. In addition, *Serinibacter* possesses phosphatidylethanolamine as a polar lipid. These data indicated that the chemotaxonomic characteristics were distinct from those of its phylogenetic neighbors (Table 107).

List of species of the genus *Serinibacter*

1. **Serinibacter salmoneus** Hamada, Iino, Tamura, Iwami, Harayama and Suzuki 2009, 2813[VP]

sal.mo′ne.us. N.L. masc. adj. *salmoneus* salmon-colored, yellowish pink, because the cells grown in liquid culture are yellowish pink.

Cells are 0.4–0.5 × 1.0–2.0 µm and nonmotile. Colonies are circular, smooth and yellowish orange, but cells grown in liquid culture are yellowish pink. Catalase-positive, oxidase-negative. The Voges–Proskauer test is positive, while the methyl red test is negative. Growth occurs at NaCl concentrations of 0–10% (w/v) but not at 15%, and the optimal NaCl concentration range for growth is 0–5%. The temperature range for growth is 10–37°C, and the optimal temperature is 28°C. The pH range for growth is 6.0–9.0, and the optimal pH is 7.0. Acid is produced from *N*-acetylglucosamine, cellobiose, D-fructose, D-galactose, gentiobiose, D-glucose, glycogen, lactose, maltose, D-mannose, methyl-α-D-glucopyranoside, methyl-β-D-xylopyranoside, starch, sucrose, trehalose, and D-xylose. Esterase lipase (C8), leucine arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase, pyrazinamidase, and pyrrolidonyl arylamidase are present, whereas alkaline phosphatase, lipase (C4), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-fucosidase, arginine dihydrolase, lysine- and ornithine decarboxylases, and tryptophan- and phenylalanine deaminases are absent. H_2S and indole are not produced. Esculin is hydrolyzed, while gelatin, urea, and DNA are not hydrolyzed. Nitrate is not reduced. The interpeptide bridge of the cell-wall peptidoglycan is L-Lys–L-Glu. The major cellular fatty acids are $C_{15:0}$ anteiso and $C_{16:0}$, followed by $C_{16:0}$ iso and $C_{17:0}$ anteiso.

Source: intestinal tract of sillago fish (*Sillago japonica*) collected from Kyonan beach on the coast of Tokyo Bay, Japan.

DNA G+C content (mol%): 70.7 (HPLC).

Type strain: Kis4-28, NBRC 104924, DSM 21801.

Sequence accession no. (16S rRNA gene): AB455532.

Bo.go.ri.el.la.ce′a.e. N.L. fem. n. *Bogoriella* type genus of the family; -*aceae* ending to denote a family; N.L. fem. pl. n. *Bogoriellaceae* the family of *Bogoriella*.

Cell morphology comprises **irregular rods, cocci** and occasionally filaments. Cells occur singly, in pairs, or in small clusters. A rod–coccus growth cycle may be expressed. Gram-stain-positive. **Nonsporeforming**. **Nonmotile** or **motile. Aerobic to microaerobic or facultatively anaerobic**. Colonies are circular, convex, and vary in their color from white to yellow. Members of the family grow well on complex organic media. Growth temperature 10–45°C. Tolerance to alkaline pH values and to NaCl in the culture medium is variable. Some of the strains are alkaliphilic and may tolerate up to 10% NaCl. **Oxidase-positive or -negative**; **catalase-positive**. The characteristic **diamino acid in the peptidoglycan is L-lysine** which corresponds to the **peptidoglycan type A4α**. The major menaquinone is **MK-8(H_4)**. The polar lipids typically comprise **diphosphatidylglycerol and phosphatidylglycerol; phosphatidylinositol or phosphatidylinositol mannoside**, and unidentified phospholipids or glycolipids may additionally be present. The cellular fatty acid profiles are dominated by **iso- and anteiso-branched-chain acids** and minor amounts of saturated straight-chain acids. Mycolic acids are absent. The family is a member of the order *Micrococcales* and currently accommodates the genera *Bogoriella* and *Georgenia*. The common 16S rRNA gene signature nucleotides of the members of the family are: nucleotides at positions 144:178 (U–G), 293:304 (G–U), 479 (U), 602:636 (C–G), 668:738 (A–U), 1003:1038 (G–C), 1027:1034 (C–G) and 1409:1491 (C–G).

DNA G+C content (mol%): 70–73.

Type genus: **Bogoriella** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 793.

Further descriptive information

The genus *Georgenia* (Altenburger et al., 2002; Li et al., 2007) is represented by three species, while the genus *Bogoriella* (Groth et al., 1997a) accommodates only one species. The members of the *Bogoriellaceae* are morphologically similar and comprise cells exhibiting coccus or rod–coccus morphologies. However, a broad spectrum of physiological properties together with the chemotaxonomic characteristics listed in Table 111 serve to distinguish the genera from one another. The phylogenetic positions of the members of the family *Bogoriellaceae* are shown in the 16S rRNA gene sequence based phylogenetic tree (Figure 142). Differentiating signature nucleotides are given in Table 112. Strains of the *Bogoriellaceae* originate from differ-

TABLE 111. Phenotypic characteristics differentiating the genera of the family *Bogoriellaceae*[a,b]

Characteristic	*Bogoriella*[c]	*Georgenia*[d]
Cell morphology	Irregular rods, coccoid cells, filaments	Short rods and cocci, rod–coccus cycle
Relationship to oxygen	Aerobic to microaerobic	Aerobic and facultatively anaerobic
Oxidase	–	+
Cell-wall diamino acid	L-Lys	L-Lys
Interpeptide bridge	L-Lys–L-Ala–L-Ala–L-Glu	L-Lys–L-Glu or L-Lys–L-Ala–L-Glu
Predominant cellular fatty acids	$C_{15:0}$ anteiso, $C_{17:0}$ anteiso	$C_{15:0}$ anteiso, $C_{15:0}$ iso, $C_{14:0}$ iso
Polar lipids	PG, DPG, PI, 1 PL	DPG PG; PI or PIM, PL, GL
DNA G+C content (mol%)	70	70–73

[a]Symbols: +, positive; –, negative.

[b]Abbreviations: DPG, diphosphatidylglycerol; GL, unidentified glycolipid; PG, phosphatidylglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannoside; PL, unidentified phospholipid.

ent habitats: soda soil (*Bogoriella*), soil from a forest (*Georgenia ruanii*, *Georgenia thermotolerans*; Li et al., 2007; Hamada et. al., 2009a) and from a medieval wall painting in case of *Georgenia muralis* (Altenburger et al., 2002).

Taxonomic comments

The family *Bogoriellaceae* was established by Stackebrandt and Schumann (2000) for the monospecific genus *Bogoriella*. At that time it had become evident that the phylogenetic lineage of *Bogoriella caseilytica* branches among other lineages within the suborder *Micrococcineae* described as individual families. The subsequent descriptions of the genera *Salana* (von Wintzingerode et al., 2001), *Georgenia* (Altenburger et al., 2002) and *Ruania* (Gu et al., 2007) indicated a close phylogenetic relationship between these three genera and the genera *Beutenbergia* (Groth et al., 1999) and *Bogoriella*, based on the levels of 16S rRNA gene sequence similarities and the correspondence in the patterns of 16S rRNA gene sequence signature nucleotides. But the update of the patterns of 16S rRNA gene sequence signature nucleotides revealed that the genera *Beutenbergia*, *Georgenia* and *Salana* were members of the new family *Beutenbergiaceae*, and the genus *Bogoriella* remained the only member of the family *Bogoriellaceae* (Zhi et al., 2009). With the subsequent emendation of the descriptions of the families *Beutenbergiacea* and *Bogoriellaceae* by Hamada et al. (2009b), the genus *Georgenia* was grouped into the family *Bogoriellaceae*. The family *Beutenbergiaceae* was defined mainly on the basis of the following 16S rRNA gene sequence signature pattern consisting of nucleotides at positions 144:178 (C–G), 280 (U), 293:304 (G–U), 668:738 (A–U), 1003:1038 (G–U), 1027:1034 (U–A) and 1414:1486 (U–A), and comprised the genera *Beutenbergia*, *Salana* and *Serinibacter* (Hamada et al., 2009b). Recently the genus *Miniimonas* (Ue et al., 2011) was included into this family as its pattern of signature nucleotides was in accordance with that described for the *Beutenbergiaceae*. The genus *Ruania* could not be affiliated to one of the above mentioned related families due to the differences in the 16S rRNA gene sequence signature nucleotides (Hamada et al., 2009b).

Genus I. **Bogoriella** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 793[VP]

Ingrid Groth

Bo.go.ri.el′la. N.L. dim. fem. n. *Bogoriella* named after Lake Bogoria, Kenya.

Cells are irregularly shaped rods or cocci (0.5–0.8 × 1.0–2.5 µm). **Filaments**, up to 10 µm, may appear. Cells occur singly, in pairs, or in small clusters. Gram-stain-positive. Not acid fast. **Endospores are not formed**. **Nonmotile**. **Aerobic to microaerobic**. Colonies are circular, smooth, slightly convex, glistening, and pale to intense yellow. Growth temperature 28–37°C. **Alkaliphilic.** The optimum initial pH for growth in liquid medium A ranges from 8.8–10.1. NaCl in the alkaline medium A is well tolerated up to 8%. **Oxidase-negative; catalase-positive**. The **peptidoglycan type is A4α** with **L-lysine** as the diagnostic diamino acid and an **L-Lys–L-Ala–L-Ala–L-Glu interpeptide bridge.** The **acyl type is acetyl**. **Galactose** is the only whole-cell sugar. The predominant respiratory quinone is **MK-8(H_4).** The phospholipids are **phosphaditylglycerol, diphosphaditylglycerol, phosphaditylinositol, and an unknown phospholipid.** The cellular fatty acid profile is dominated by the occurrence of **anteiso-branched-chain acids**; iso-branched-chain acids occur in minor amounts Mycolic acids are absent. Based on 16S rRNA gene sequence comparison, *Bogoriella* is most closely related to the genera *Georgenia* and *Beutenbergia* (Figure 142). The 16S rRNA gene signature nucleotides that differentiate the genus from the other genus of the *Bogoriellaceae* are listed in Table 11.

DNA G+C content (mol%): 70.

Type species: **Bogoriella caseilytica** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 793[VP].

Further descriptive information

Currently the genus is represented by the only species, *Bogoriella caseilytica*, and accommodates a single strain. 16S rRNA gene sequence comparison shows that this strain forms a common branch in the 16S rRNA gene tree of the suborder *Micrococcineae* (Stackebrandt et al., 1997) with the three species of *Georgenia* (Altenburger et al., 2002; Li et al., 2007; Hamada et al., 2009a) within the cluster of the family *Bogoriellaceae* (Stackebrandt and Schumann, 2000) (Figure 142, chapter on *Beutenbergiaceae*, above). *Bogoriella caseilytica* shares 94.7–95.0% 16S rRNA gene sequence similarity with the type strains of *Georgenia muralis* (Altenburger et al., 2002) and *Georgenia ruanii* (Li et al., 2007). The sequence similarities to other related genera are 93.9% (*Beutenbergia*), 93.2% (*Ruania*), and 92.9% (*Salana*), respectively.

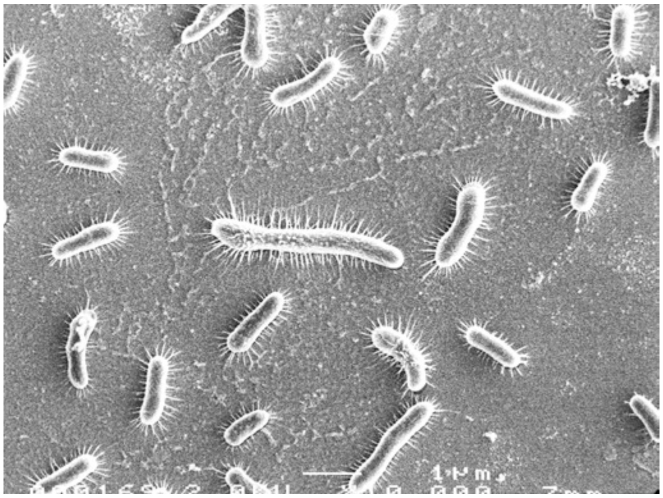

FIGURE 147. Scanning electron micrograph of cells from a 48-h-old culture of *Bogoriella caseilytica* DSM 11294^{T} grown at 28°C on solid medium A. Bar = 1 μm.

Interestingly, a comparable level of 16S rRNA gene sequence similarity (93.7% or 92.8%) is also found between *Bogoriella* and members of the genera *Cellulosimicrobium* (Schumann et al., 2001) or *Promicromonospora* (Krasil'nikov et al., 1961). Both genera are members of the family *Promicromonosporaceae* (Stackebrandt et al., 1997). Scanning electron micrographs reveal that the cells of *Bogoriella caseilytica* possess spiky structures which are distributed over the whole surface of each cell (Figure 147). The peptidoglycan is characterized by the presence of lysine, alanine, and glutamic acid at a molar ratio of 1.0:4.3:2.1 and represents a new variation of the peptidoglycan type A4α (Schleifer and Kandler, 1972) with an L-Lys–L-Ala–L-Ala–L-Glu interpeptide bridge. *Bogoriella caseilytica* grows well on alkaline complex media containing peptone and casein as nitrogen sources and utilizes a broad spectrum of carbon sources.

Enrichment and isolation procedures

Bogoriella caseilytica can be enriched using solidified or liquid medium A (Duckworth et al., 1996) which contains (g/l): glucose, 10.0; peptone (Difco), 5.0; yeast extract (Difco), 5.0; KH_2PO_4, 1.0; $MgSO_4 \cdot 7H_2O$, 0.2; NaCl, 40.0; Na_2CO_3; 10.0, and agar, 20.0; pH 9.6, and incubation temperatures 28–37°C. It is important for the preparation of medium A that NaCl and Na_2CO_3 have to be sterilized separately. They have to be added to the remaining compounds at 60°C before the agar medium is poured into the Petri dishes. A cultivation of the strain is also possible for a limited number of transfers on complex organic media like Bacto nutrient agar (Difco) at a neutral pH value. However, under these conditions growth is reduced. *Bogoriella caseilytica* was isolated from soda soil (pH 10.0) near Lake Bogoria in the Kenyan–Tanzanian Rift Valley using a standard dilution plate procedure and medium A.

Maintenance procedures

Cultures of *Bogoriella caseilytica* are maintained for laboratory cultivation by serial transfers on solidified or in liquid medium A. Growth on agar slants in screw-capped tubes can be kept for about 2–4 weeks at 4°C. Long-term preservation of liquid cultures supplemented with 5% dimethylsulfoxide is recommended in the vapor phase of liquid nitrogen (−140°C).

Differentiation of the genus *Bogoriella* from other genera

The genus *Bogoriella* can be clearly differentiated from the genus *Georgenia* of the family *Bogoriellaceae* by unique morphological, physiological, and chemotaxonomic characteristics; among them are the unusual spiky structures on the cell surfaces which have so far not been reported before in coryneform actinobacteria. *Bogoriella* shares with strains of the genera *Georgenia* (Altenburger et al., 2002; Li et al., 2007; Hamada et al., 2009a), *Beutenbergia* (Groth et al., 1999), *Serinibacter* (Hamada et al., 2009b), *Ruania* (Gu et al., 2007), and *Demetria* (Groth et al., 1997b) the combination of the peptidoglycan type A4α (Schleifer and Kandler, 1972) and MK-8(H_4) as predominating menaquinone. However, while *Bogoriella* has an L-Lys←L-Ala←L-Ala←L-Glu interpeptide bridge, in *Georgenia* two different structures may occur, e.g. L-Lys←L-Glu or L-Lys←L-Ala←L-Glu, respectively. *Beutenbergia* and *Serinibacter* share with *Georgenia muralis* (Altenburger et al., 2002) the interpeptide bridge of L-Lys←L-Glu, while *Ruania* has an interpeptide bridge consisting of L-Lys←Gly←L-Glu←L-Glu which represents a novel murein type (Gu et al., 2007). *Demetria* (family *Dermacoccaceae*, Stackebrandt and Schumann, 2000; Zhi et al., 2009) is characterized by an L-Lys←Ser←D-Asp interpeptide bridge and can be additionally distinguished from *Bogoriella* by its remote phylogenetic relationship (90.4% 16S rRNA gene sequence similarity) and a broad spectrum of physiological characteristics. The genera *Cellulosimicrobium* and *Promicromonospora* can be also readily distinguished from *Bogoriella* by the formation of hyphae, the structure of the peptidoglycan, the presence of MK-9(H_4) as major menaquinone and numerous further phenotypic properties (Schumann et al., 2001; Krasil'nikov et al., 1961).

Taxonomic comments

The genus *Bogoriella* has been established in 1997 to accommodate an unusual actinobacterial strain from an alkaline habitat. At that time, the low degree of 16S rRNA gene similarity with other members of the order *Actinomycetales* (less than 95%) did not justify an affiliation to a higher taxonomic rank for a single strain. However, in 2000, the family *Bogoriellaceae* was established by Stackebrandt and Schumann to accommodate the monospecific genus *Bogoriella* as it became evident that the phylogenetic lineage of *Bogoriella caseilytica* branches among other lineages within the suborder *Micrococcineae* (since elevated to order *Micrococcales* in the taxonomic outline to the present volume) described as individual families. The descriptions of the genera *Beutenbergia*, *Georgenia*, *Ruania* and *Salana* revealed a close phylogenetic relationship of these genera with *Bogoriella*. However, with the update of the structure and 16S rRNA gene sequence based definition of higher ranks of the class *Actinobacteria* it was obvious that the genera *Beutenbergia*, *Georgenia* and *Salana* should be grouped into the new family *Beutenbergiaceae* (Zhi et al., 2009). *Bogoriella* continued to be the only genus in the family *Bogoriellaceae* until the emendation of the descriptions of the families *Beutenbergiaceae* and *Bogoriellaceae* by Hamada et al. (2009b). According to Hamada et al. (2009b) the family *Bogoriellaceae* accommodates the genera *Bogoriella* and *Georgenia* while the family *Beutenbergiaceae* contains the genera *Beutenbergia*, *Salana*, *Serinibacter* and the genus *Miniimonas* which was recently included in this family (Ue et al., 2011).

List of species of the genus *Bogoriella*

1. **Bogoriella caseilytica** Groth, Schumann, Rainey, Martin, Schuetze and Augsten 1997a, 793[VP]

ca. sei.ly′ti.ca. L. n. *caseus* cheese; N.L. adj. *lyticus -a -um* (from Gr. adj. *lutikos -ê -on*), able to loosen, able to dissolve; N.L. fem. adj. *caseilytica* loosening or dissolving casein.

Description is the same as for the genus. In addition, the strain shows the following phenotypic characteristics. The following organic acids are not used as sole carbon sources: acetate, aconitate, benzoate, citrate, formate, malate, succinate, and DL-tartrate. Acids are produced from L-arabinose, D-cellobiose, dextrin, D-fructose (weak), D-galactose, D-glucose, D-glucitol (weak), glycerol, inulin, lactose (weak), maltose (weak), D-mannitol (weak), D-mannose, D-raffinose (weak), L-rhamnose, D-ribose, salicin, sucrose (weak), potato starch, trehalose, and D-xylose. Starch, casein, esculin, and gelatin are hydrolyzed. Adenine, hippurate, hypoxanthine, Tween 80, tyrosine, urea, and xanthine are not decomposed. Furthermore, the following substrates provided in the GP microplates (Biolog) are used as sole carbon sources: amygdalin, L-arabinose, D-arabitol, arbutin, cellobiose, α- and β-cyclodextrin, D-fructose, L-fucose, D-galactose, gentiobiose, α-D-glucose, glycerol, glycogen, α-hydroxybutyric acid, α-D-lactose, lactulose, maltose, maltotriose, D-mannitol, D-mannose, D-melezitose, D-melibiose, methyl-β-D-galactoside, 3-methyl-glucose, methyl-β-D-glucoside, methyl-α-D-mannoside, palatinose, D-raffinose, D-ribose, salicin, D-sorbitol, stachyose (weak), sucrose, D-tagatose, D-trehalose, turanose, D-xylose, methyl pyruvate, and pyruvic acid. Nitrate is not reduced to nitrite. Hydrogen sulfide is produced (weak); indole is not produced. Methyl red and Voges–Proskauer reactions are negative. 48-h-old cultures of *Bogoriella caseilytica* display positive enzymic reactions in the API ZYM enzyme assay (bioMerieux) for acid phosphatase, alkaline phosphatase, esterase (C4), esterase-lipase (C8), leucine arylamidase, β-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase. Chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-glucuronidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase are negative. Cells are susceptible to the following antibiotics (μg/disc): ampicillin (10) chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), lincomycin (2), neomycin (30), oxacillin (5), oxytetracycline (30), penicillin G (2 IU/disc), polymyxin B (2 IU/disc), rifampin (2), and streptomycin (10). The cellular fatty acid profile is characterized by the predominance of $C_{15:0}$ anteiso and minor amounts of $C_{17:0}$ anteiso, $C_{15:1}$ iso, and $C_{16:0}$ iso.

DNA G+C content (mol%): 70 (HPLC).

Type strain: HKI 0088, ATCC 700413, CIP 105404, DSM 11294, JCM 11479.

Sequence accession no. (16S rRNA gene): Y09911.

Genus II. **Georgenia** Altenburger, Kämpfer, Schumann, Vybiral, Lubitz and Busse 2002, 880[VP] emend. Li, Xu, Schumann, Zhang, Pukall, Xu, Stackebrandt and Jiang 2007, 1426

Hans-Jürgen Busse

Ge.or.gen′i.a. N.L. fem. n. *Georgenia* referring to the village St Georgen in Styria (Austria), where strains 1A-C[T] and 3A-1 were isolated.

Cells may exhibit a rod–coccus growth cycle. Rods and cocci occur singly or in small clusters. Cocci are 1 μm in diameter; rods are 1–2 ×0.5–1 μm. Gram-stain-positive, non-spore-forming, motile and nonmotile. Growth occurs under both aerobic and anaerobic conditions. Oxidase and catalase positive. Peptidoglycan type is A4α with L-Lys ← L-Glu or L-Lys–L-Ala–L-Glu as the interpeptide bridge (murein type A11.54 or A11.35). Quinone system is menaquinone MK-8(H_4). Polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol mannoside or phosphatidylinositol together with unidentified phospholipids, and one unknown glycolipid. The predominant fatty acid is $C_{15:0}$ anteiso; significant amounts of $C_{15:1}$ anteiso, $C_{15:0}$ iso and $C_{14:0}$ iso are present. Polyamine content is low. Major polyamines are spermidine and spermine. Phylogenetically, this genus is a member of the family *Bogoriellaceae*, order *Micrococcales*, class *Actinobacteria*.

DNA G+C (mol%): 70–73.

Type species: **Georgenia muralis** Altenburger, Kämpfer, Schumann, Vybiral, Lubitz and Busse 2002, 880[VP].

Further descriptive information

The genus *Georgenia* was described for two Gram-stain-positive, yellow-pigmented strains which had been isolated from a medieval wall painting in St Georgen, Styria, Austria (Altenburger et al., 2002). Similarity values in the 16S rRNA gene sequences indicate a moderate relatedness to representatives of the genera *Cellulomonas*, *Cellulosibacterium*, *Beutenbergia*, *Bogoriella*, and *Oerskovia*. The two strains of *Georgenia muralis* exhibit a quinone system with the major compound MK-8(H_4). The peptidoglycan type is A4α with an interpeptide bridge L-Lys ← L-Glu. In the polar lipid profile, diphosphatidylglycerol is predominating. Moderate to minor amounts of phosphatidylinositol-mannosides, two unknown phospholipids, an unknown glycolipid, and phosphatidylglycerol are present as well. The yellow pigmentation is based on at least five different compounds. The fatty acid profile is predominated by the presence of methyl-branched fatty acids of the iso- and anteiso-type with the major compound $C_{15:0}$ anteiso. Differential characteristics for the *Georgenia* versus some related genera are shown in Table 113.

Based on high 16S rRNA gene sequences similarities two suspected, but so far not described, members of the genus are apparently present in institutional collections; these include *Georgenia* sp. (99.6% similarity; accession no AB094466) isolated from sub-seafloor sediment of the sea of Okhotsk (Inagaki et al., 2003) and *Georgenia* sp. T04-04 (97.0% similarity; accession no: AY880044) cultivated from within oral squamous cell carcinoma tissue removed from a 96-year-old female patient (Hooper et al., 2006).

TABLE 113. Characteristics differentiating *Georgenia* from related taxa[a]

Characteristic	*Georgenia*[b]	*Beutenbergia*[c]	*Bogoriella*[d]	*Cellulomonas*[e]	*Cellulosimicrobium*[f]	*Demetria*[g]	*Salana*[h]
Cell morphology	Rod–coccus	Rod–coccus	Irregular rods, coccoid	Branched rods	Rod-shaped	Coccoid, short rods	Rod-shaped-circular or club-like
Major menaquinone	MK-8(H_4)	MK-8(H_4)	MK-8(H_4)	MK-9(H_4)	MK-9(H_4)	MK-8(H_4)	MK-8(H_4)

Enrichment and isolation procedures

For isolation, temperatures of approximately 28°C, neutral pH, and media with rather low nutrient content such as R2A* or ISP 2† agar are preferred by strains of this genus.

Pathogenicity

Nothing is known about pathogenicity of *Georgenia muralis*, *Georgenia ruanii*, or *Georgenia* sp., but due to its source of isolation, *Georgenia* sp. T04-04 should be carefully examined for its potential to act as an opportunistic pathogen.

List of species of the genus *Georgenia*

1. **Georgenia muralis** Altenburger, Kämpfer, Schumann, Vybiral, Lubitz and Busse 2002, 880[VP]

mu.ra′lis. L. adj. *muralis*, *-le* pertaining or belonging to walls.

Morphological, chemotaxonomic, and general characteristics are as described for the genus. Colonies reach a maximum diameter of 2 mm. They are yellow pigmented, transparent, circular, and convex. Good growth occurs at NaCl concentrations up to 5% (w/v), with weak growth at 7% (w/v) NaCl. Growth is observed at pH 6–9.

N-Acetyl- D-glucosamine, L-arabinose, *p*-arbutin, D-cellobiose, D-fructose, D-galactose, gluconate, D-glucose, D-maltose, α-D-melibiose, sucrose, salicin, D-trehalose, D-xylose, and D-mannitol are assimilated. L-Rhamnose, D-ribose, adonitol, *i*-inositol, maltitol, D-sorbitol, putrescine, acetate, propionate, *cis*-aconitate, *trans*-aconitate, adipate, 4-aminobutyrate, azelate, citrate, fumarate, glutarate, DL-3-hydroxybutyrate, itaconate, DL-lactate, L-malate, mesaconate, oxoglutarate, pyruvate, suberate, L-alanine, β-alanine, L-aspartate, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-serine, L-tryptophan,3-hydroxybenzoate, 4-hydroxybenzoate, and phenylacetate are not assimilated. Assimilation of D-mannose is variable. *p*-Nitrophenyl (pNP) β-D-galactopyranoside, pNP β-D-glucuronide, pNP α-D-glucopyranoside, pNP β-D-glucopyranoside, bis-pNP phosphate, pNP phenylphosphonate, L-alanine *p*-nitroanilide (pNA), and L-proline pNA are hydrolyzed. pNP Phosphorylcholine, 2-deoxythymidine-5′-pNP phosphate, and L-glutamate γ-3-carboxy-pNA are not hydrolyzed. Esculin, cellulose azur, and potato starch are hydrolyzed. α-Cellulose, casein, and Tween 80 are not decomposed. Nitrate is reduced to nitrite. Negative for H_2S production, indole production, and urease activity. Good growth occurs at 28°C and 37°C, weak growth at 4°C, and no growth at 44°C. An unidentified compound is present in the fatty acid profile in significant amounts.

Source: medieval wall painting in the church of St Georgen in Styria, Austria.

DNA G+C content (mol%): 70 (HPLC).

Type strain: 1A-C, CCM 4963, DSM 14418, JCM 12241, NBRC 103560.

Sequence accession no. (16S rRNA gene): AB455495, X94155.

2. **Georgenia ruanii** Li, Xu, Schumann, Zhang, Pukall, Xu, Stackebrandt and Jiang 2007, 1426[VP]

ru.a′ni.i. N.L. gen. n. *ruanii* of Ruan, named in honor of Ji-Sheng Ruan (1926–), a Chinese microbiologist who devotes himself to the study of actinomycete taxonomy.

Displays the following properties in addition to those described above for the genus. Colonies are 1.1–1.2 mm in diameter, circular, entire, slightly convex, opaque, and pale white–yellow to straw-colored on ISP 2 agar. Cells are short-rod-shaped, 0.5–0.8 × 1.4–2.0 µm in size, and motile (by means of a single flagellum at each end of the cell). Chemoorganotrophic, with respiratory-type metabolism. Endospores and polyhydroxyalkanoate are not formed. Does not grow in the presence of sodium chloride at concentrations above 5%. Temperature range for growth is 10–37°C, with optimum growth at 28–30°C. pH Range for growth is 6.5–10.0, with optimum growth at pH 7.0. Tests for the hydrolysis of gelatin, for melanin production, H_2S production and indole production, for resistance to KCN, for milk coagulation and for peptonization are negative. Nitrate is not reduced to nitrite. Dextrin, rhamnose, fructose, glucose, arabinose, sorbose, lactose, galactose, sucrose, dulcitol, inositol, maltose, mannose, cellobiose, turanose, mannitol, melibiose, melezitose, raffinose, ribose, salicin, xylitol, adonitol, arabitol, galacturonate, and sorbitol are utilized as sole carbon and energy sources. Acid is produced from fructose, galactose, mannose, mannitol, xylose, ribose, lactose, glucose, and sucrose. Starch and esculin are hydrolyzed. Acetamide, xanthine, hypoxanthine, and Tweens 20 and 80 are degraded weakly; urea is not degraded. Lipase, lysine decarboxylase, β-glucosidase, *N*-acetyl- β-glucosaminidase, β-galactosidase, α-maltosidase, and L-aspartic arylamidase tests are positive, while arginine dihydrolase, ornithine decarboxylase, α-galactosidase, and β-glucuronidase tests are negative. Resistant to oleandomycin and nalidixic acid, but sensitive to penicillin G, vancomycin, polymyxin B, erythromycin, terramycin, aureomycin, tetracycline, streptomycin sulfate, novobiocin, gentamicin, and chloramphenicol. The peptidoglycan type is A4 (L-Lys–L-Ala–L-Glu). The cell-wall sugars are galactose and rhamnose. The polar lipids are phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and an unknown phospholipid. The menaquinones are MK-8(H_4), MK-7(H_4), and MK-9(H_4) (90:2:1). The cellular fatty acid profile consists mainly of $C_{15:0}$ anteiso (78.3%) and $C_{15:0}$ iso (14.9%), with other minor components, including $C_{17:0}$ anteiso (1.6%), $C_{14:0}$ (1.0%), $C_{15:1}$ anteiso (1.0%), $C_{16:0}$ (1.0%), $C_{13:0}$ anteiso (0.7%), $C_{16:0}$ iso (0.6%), $C_{17:0}$ iso (0.5%), $C_{14:0}$ iso (0.5%), and $C_{13:0}$ iso (0.1%).

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: YIM 004, CCTCC AB 204065, DSM 17458, JCM 15130, KCTC 19029, NBRC 103883.

Sequence accession no. (16S rRNA gene): DQ203185.

3. **Georgenia thermotolerans** Hamada, Tamura, Ishida and Suzuki 2009a, 1878[VP]

ther.mo.to′le.rans. Gr. n. *therme* heat; L. pres. part. *tolerans* tolerating; N.L. part. adj. *thermotolerans* able to tolerate high temperatures.

*R2A: 0.5 g/l yeast extract, 0.5 g/l casein hydrolysate, 0.5 g/l, glucose, 0.5 g/l starch, 0.3 g/l K_2HPO_4, 0.024 g/l $MgSO_4$, 0.3 g/l Na_2-pyruvate, 15 g/l agar, pH 7.2 ± 0.2.

†ISP 2 agar: 4 g/l yeast extract (Difco), 10 g /l malt extract (Difco), 4 g/l dextrose (Difco), 50 g/l NaCl, 20g/l agar, pH 7.4 ± 0.2.

Displays the following properties in addition to those described above for the genus. Colonies are 1–2 mm in diameter, circular, opaque, smooth and whitish–yellow. Cells are irregular, rod-shaped, 0.5–0.7 × 1.0–2.0 µm in size, and motile. Good growth occurs under both aerobic and anaerobic conditions and in the presence of sodium chloride at concentrations of 0–5%. Moderate growth occurs at 7% NaCl and no growth at 10% NaCl. Temperature range for growth is 10–45°C, optimum growth at 28°C. pH range for growth is 6.0–9.0, optimum growth at pH 7.0. Acid is produced from D-ribose, D-xylose, D-glucose, methyl α-D-glucopyranoside, amygdalin, arbutin, salicin, D-cellobiose, maltose and sucrose. No acid production occurs from L-arabinose, L-xylose, D-mannose, D-mannitol, melibiose, trehalose, D-raffinose, starch or glycogen. Esterase (C4), esterase lipase (C8), leucine aminopeptidase, phosphohydrolase, β-glucuronidase, β-glucosidase, α-glucosidase, pyrazinamidase and pyrrolidonyl arylamidase are present; alkaline phosphatase, lipase (C14), valine aminopeptidase, cysteine aminopeptidase, trypsin, chymotrypsin, α-galactosidase, β-galactosidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, α-fucosidase, arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase and tryptophan deaminase are absent. H_2S and indole are not produced. Aesculin, gelatin and urea are not hydrolyzed. Nitrate is reduced to nitrite. The peptidoglycan is of the A4α type with aspartic acid. The cell-wall sugar is galactose. Major polar lipids are diphosphatidylglycerol, phosphatidylglycerol and phosphatidylinositol mannosides. The predominant fatty acids are: $C_{15:0}$ anteiso (89.3%), $C_{14:0}$ iso (6%) and $C_{15:0}$ iso (4.7%).

Type strain was isolated from forest soil in Iriomote Island, Japan.

DNA G+C content (mol%): 73.0 (HPLC).

Type strain: TT02-04, NBRC 104148, DSM 21501.

Sequence accession no. (16S rRNA gene): AB436534.

Family IV. **Brevibacteriaceae** Breed 1953b, 13^AL emend. Zhi, Li and Stackebrandt 2009, 597^VP

Michael Goodfellow and Martha E. Trujillo

Brev.i.bac.te.ri.a.ce′a.e. N.L. neut. *Brevibacterium* type genus of the family; suff *-aceae* ending to denote a family; N.L. fem. pl. n *Brevibacteriaceae* the *Brevibacterium* family.

The family contains the genus *Brevibacterium*. A distinct pattern of 16S rRNA signatures shown by members of the family, namely **120(A), 131:231 (C–G), 196 (A), 342:347 (C–G), 444:490 (A–U), 580:761 (C–G), 602:636 (C–G), 670:736 (U–A), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (C), 950:1231 (U–A), 1047:1210 (G–U), 1109 (C), 1145 (A), 1309:1328 (G–C), 1361 (G), 1383 (C)**, distinguishes it from all other families classified in the order *Micrococcales*. Additional properties of the family are found in the genus description.

DNA G+C content (mol%): 55–70.

Type genus: **Brevibacterium** Breed 1953b, 13^AL emend. Collins, Jones, Keddie and Sneath 1980, 6.

Further descriptive information

The suborder *Micrococcineae* (Breed 1953b) emend. Zhi et al. 2009 has been elevated into the order *Micrococcales* (see section on this order, above). The genus *Brevibacterium* forms a distinct clade in the 16S rRNA *Micrococcales* tree (see section on the order *Micrococcales*) and can be distinguished from other families in the order by using chemotaxonomic properties, notably on the basis of menaquinone composition and polar lipid and polyamine patterns (Stackebrandt and Schumann, 2000).

Genus I. **Brevibacterium** Breed 1953a, 13^AL emend. Collins, Jones, Keddie and Sneath 1980, 6

Martha E. Trujillo and Michael Goodfellow

Bre.v.i.bac.te′ri.um. L. adj. *brevis* short; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Brevibacterium* a short rodlet.

Aerobic, **catalase-positive, non-acid-fast, asporogenous actinomycetes which have a rod–coccus cell cycle when grown on complex media**. Usually nonmotile, but some species show motility. **Both rod and coccoid forms are Gram-stain-positive, but some strains and older cultures decolorize readily**. Cells are variable in length but generally are 0.6–1.0 µm in diameter; those from older cultures (3–7 d) are composed mainly or entirely of coccoid cells or coccobacilli. On transfer to a suitable fresh medium, these forms grow out to give the irregular, slender rods characteristic of exponential phase cultures. **Many cells are arranged at an angle to give V-forms**. **Primary branching may occur but not a true mycelium. Respiratory mode of metabolism.** Optimum growth temperature is 20–37°C depending on the species and strain. Grows well on peptone-yeast extract agar at neutral pH. Little or no acid is produced from glucose or other carbohydrates in a peptone medium. Proteinases produced. **The cell-wall peptidoglycan contains *meso*-diaminopimelic acid as the diamino acid and is of the A1γ type. Contains dihydrogenated menaquinones with eight isoprene units as the predominant isoprenologue and major proportions of branched cellular fatty acids, notably $C_{15:0}$ anteiso and $C_{17:0}$ anteiso**. Mycolic acids are absent.

Isolated from clinical material, dairy products, poultry, and marine and terrestrial habitats.

DNA G+C content (mol%): 55–70.

Type species: **Brevibacterium linens** (Wolff 1910) Breed 1953a, 13^AL emend. Collins, Jones, Keddie and Sneath 1980, 7 ("*Bacterium linens*" Wolff 1910).

Further descriptive information

Phylogeny. The genus *Brevibacterium* forms a distinct line of descent within the high G+C containing actinomycetes (Cai and Collins, 1994; Stackebrandt et al., 1997; Zhi et al., 2009). The 24 species assigned to the genus form a monophyletic group in the 16S rRNA gene tree (Figure 148) and share sequence similarities which range from 92.5% between *Brevibacterium aurantiacum* and *Brevibacterium paucivorans*, to 99.8% between *Brevibacterium sanguinis* and *Brevibacterium celere*. DNA–DNA relatedness experiments have not been carried out between the type strains of the two latter species which were described around the same time in 2004.

Cell morphology. Brevibacteria grow on a range of media though morphology and staining reactions are best seen on EYGA medium (Cure and Keddie, 1973). Strains tend to show a distinct rod–coccus cycle when grown on complex media (Collins, 2006; Collins et al., 1980). Both young (6–24 h) and older (3–7 d) cultures should be examined as cell shape (Figure 149) and staining properties change during the growth cycle (Crombach, 1974; Cure and Keddie, 1973; Mulder and Antheumisse, 1963). Coccoid cells are mainly found in older cultures and when transferred to fresh media give rise to slender irregular rods. Coccoid and rod-shaped cells are Gram-stain-positive but generally decolorize with age (Jones and Keddie, 1986). Members of the genus are typically nonmotile, though motility has been detected in *Brevibacterium album* (Tang et al., 2008), *Brevibacterium iodinum* (Colwell et al., 1969), and *Brevibacterium samyangense* (Lee, 2006).

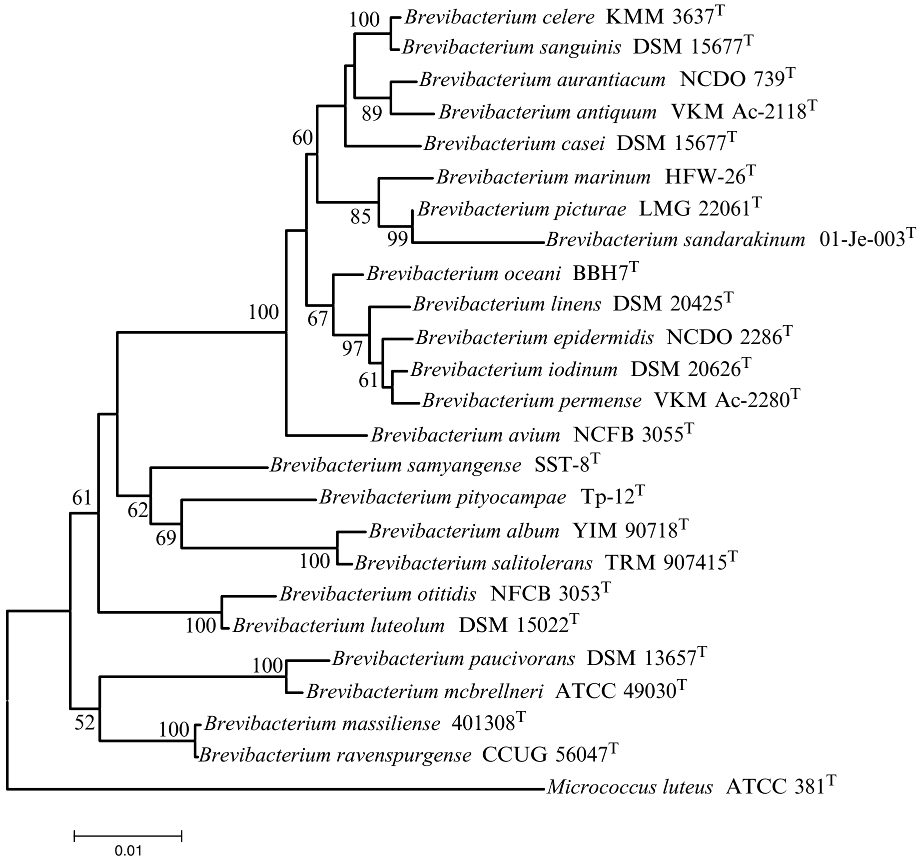

FIGURE 148. Neighbor-joining tree based on 16S rRNA gene sequences showing the phylogenetic relationships of *Brevibacterium* species. Bootstrap values are shown at branching points. *Micrococcus luteus* ATCC 381^T was used as outgroup. Bar = 1 substitution per 100 nucleotides.

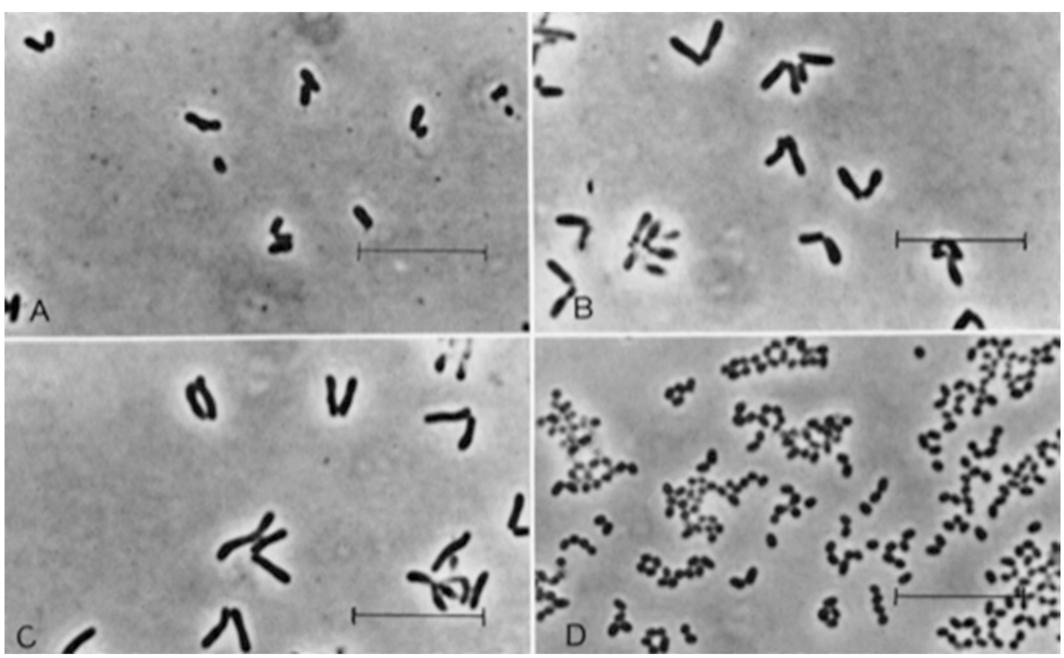

FIGURE 149. *Brevibacterium linens* (ATCC 9175) when grown on medium EYGA at 25°C; inoculum coccoid cells as in (D). (A) After 6 h, showing outgrowth of rods from coccoid cells; (B) after 12 h; (C) after 24 h; and (D), after 3 d. Bars = 10 µm. (Reproduced with permission from Keddie and Jones, 1981. The genus *Brochothrix* (formerly *Microbacterium thermosphactum*, McLean and Sulzbacher). *In* The Prokaryotes: a Handbook on Habitats, Isolation, and Identification of Bacteria (edited by Starr, Stolp, Trüper, Balows and Schlegel). Springer, New York, pp. 1866–1869.)

Chemotaxonomy. The cell-wall peptidoglycan contains *meso*-diaminopimelic acid (Collins et al., 1983a; Fiedler et al., 1981; Kämpfer et al., 2010; Keddie and Cure, 1977, 1978; Pascual and Collins, 1999; Tang et al., 2008; Yamada and Komagata, 1972b) and is of the A1γ type (Schleifer and Kandler, 1972). A unique feature of *Brevibacterium paucivorans* is the presence of glycine and glutamic acid as non-peptidoglycan components of the cell wall (Wauters et al., 2001). Galactose is present in the cell wall of some species such as *Brevibacterium album* (Tang et al., 2008), *Brevibacterium avium* (Pascual and Collins, 1999), *Brevibacterium casei*, and *Brevibacterium epidermidis* (Sharpe et al., 1977, 1978). Teichoic acids were initially detected in the cell walls of *Brevibacterium casei* (Fiedler and Bude, 1989), *Brevibacterium epidermidis* (Fiedler and Bude, 1989), *Brevibacterium iodinum* (Anderton and Wilkinson, 1980) and *Brevibacterium linens* (Fiedler et al., 1981) but have been found in additional *Brevibacterium* species (Gavrish et al., 2005).

Brevibacterium species have similar fatty acid patterns. All contain major amounts of anteiso- and iso-methyl branched acids together with small amounts of straight-chain saturated acids. The major components are 12-methyltetradecanoic ($C_{15:0}$ anteiso) and 14-methylhexadecanoic ($C_{17:0}$ anteiso) acids (Bousfield et al., 1983; Bowie et al., 1972; Collins et al., 1980, 1983a). These fatty acids usually account for over 75% of the total fatty acid composition (Bhadra et al., 2008; Funke and Carlotti, 1994; Gruner et al., 1993; Ivanova et al., 2004; Kati et al., 2010) though not in species such as *Brevibacterium mcbrellneri* (McBride et al., 1993), *Brevibacterium otitidis* (Wauters et al., 2003), and *Brevibacterium paucivorans* (Wauters et al., 2001). In contrast, mycolic acids are not found in brevibacteria (Goodfellow et al., 1976; Heyrman et al., 2004; Keddie and Cure, 1977; Lee, 2006).

Menaquinones are the sole respiratory quinones present in the cell membranes of brevibacteria. The major component is usually dihydrogenated menaquinone with eight isoprene units [MK-8(H_2)] (Collins et al., 1980, 1983a; Heyrman et al., 2004; Kämpfer et al., 2010; Lee, 2006, 2008), though smaller amounts of other components such as MK-8, MK-7(H_2), and MK-9(H_2) may be present (Collins et al., 1979, 1980, 1983a). In contrast, *Brevibacterium casei* and *Brevibacterium linens* contain comparable amounts of MK-7(H_2) and MK-8(H_2) (Collins et al., 1983a).

Diphosphatidylglycerol (DPG) and phosphatidylglycerol (PG) usually feature as major components in brevibacterial polar lipid patterns (Bhadra et al., 2008; Collins et al., 1983a; Kämpfer et al., 2010). Collins et al. (1980) reported both of these lipids and a glycolipid, dimannosyldiacylglycerol, in strains of *Brevibacterium iodinum* and *Brevibacterium linens*. Some species also contain phosphatidylinositol (PI) (Collins et al., 1980, 1983a; Heyrman et al., 2004; Lee, 2008), though the presence of this component has been shown to vary with cultural conditions (Jones and Keddie, 1986). In addition to DPG and PG, an unidentified glycolipid has been detected in *Brevibacterium picturae* (Heyrman et al., 2004) and *Brevibacterium sandarakinum* (Kämpfer et al., 2010). Cadavarine and putrescine are characteristic components of brevibacterial polyamine patterns (Altenburgera et al., 1996; Kämpfer et al., 2010).

Colony morphology. Opaque, white or pale orange, convex colonies (0.5–1.0 mm in diameter) with entire edges and smooth, shiny surfaces are formed within 2 d on nutrient agar. Colonies become larger (2.0–4.0 mm in diameter) after 4–7 d (Jones and Keddie, 1986). Opaque gray-white, convex colonies with smooth, shiny surfaces up to 2 mm in diameter are formed on blood agar after 24 h; they later increase in size and turn slightly greenish or yellowish in color (Funke et al., 1997). Collins et al. (1983a) described colonies of *Brevibacterium casei* as gray-white in color, but in an earlier study of the same strains, Sharpe et al. (1976) recorded the slow production of a brown, water-soluble pigment when the organisms were cultured on milk agar.

Brevibacterium linens forms yellow to deep orange-yellow colonies when grown on a range of media, with pigment production in most strains being light-dependent (Crombach, 1974; Mulder et al., 1966). Jones et al. (1973) suggested that the pigment of *Brevibacterium linens* was a carotenoid which could be recognized by distinctive color reactions occurring when pigmented growth was treated with either glacial acetic acid or solutions of strong bases. The pigments of *Brevibacterium linens* were subsequently shown to consist of the aromatic carotenoids 3,3′-dihydroxyisorenieratene, isorenieratene, and 3-hydroxyisorenieratene (Kohl et al., 1983).

The characteristic metallic purple to blue color of *Brevibacterium iodinum* is due to the production of purple, extracellular crystals of the phenazine derivative iodinin on and in the colonies and adjacent medium (Collins et al., 1980; Colwell et al., 1969; Davis, 1939; Sneath, 1960). The synthesis of iodinin is enhanced on certain media such as Blood Agar Base (Difco) plates incubated at 30°C for 2 d, but is not affected by light (Sneath, 1960).

Nutritional and growth conditions. Brevibacteria grow well on routine laboratory media such as blood, nutrient, tryptone soy, yeast extract–malt extract, and yeast extract–peptone agars. They tolerate and are sometimes stimulated by the addition of NaCl to the medium (Crombach, 1974; Heyrman et al., 2004; Kati et al., 2010; Lee, 2006, 2008; Mulder et al., 1966; Sharpe et al., 1977). They grow well at neutral pH and at 30°C, though not all strains grow optimally at this temperature. *Brevibacterium linens*, for instance, grows best between 20–25°C (Keddie and Jones., 1981), *Brevibacterium avium* at 37°C (Pascual and Collins, 1999), *Brevibacterium casei* and *Brevibacterium epidermidis* between 30 and 37°C (Pitcher and Noble, 1978; Sharpe et al., 1976, 1977), and *Brevibacterium iodinum* at 28°C (Jones, 1975).

Metabolism. Brevibacteria are aerobic, catalase-positive, chemoorganotrophic actinomycetes with an oxidative type of metabolism. Most strains are proteolytic, metabolizing casein, gelatin, and milk (Bousfield, 1972; Colwell et al., 1969; Crombach, 1974; Keddie and Jones., 1981; Wauters et al., 2003). In general, acid is not produced from glucose or other carbohydrates (Bousfield, 1972; Collins et al., 1983a; Jones, 1975; Kati et al., 2010), though a range of compounds is used as sole carbon sources (Crombach, 1974; Ivanova et al., 2004; Kämpfer et al., 2010; Tang et al., 2008; Yamada and Komagata, 1972a). Several species including *Brevibacterium casei*, *Brevibacterium epidermidis*, *Brevibacterium linens*, and *Brevibacterium paucivorans* produce methanethiol from L-methionine (Pitcher and Noble, 1978; Sharpe et al., 1976, 1977, 1978; Wauters et al., 2003).

Genetics. Little is known about brevibacterial genetics, though plasmids designated pBL100 and pBL33 have been isolated from *Brevibacterium linens* strains (Kato et al., 1989; Sandoval et al., 1985) and purified (Holtz et al., 1992).

Antibiotic sensitivity. Few studies have been directed toward establishing the antibiotic sensitivity patterns of *Brevibacterium* species (Bhadra et al., 2008; Colwell et al., 1969; Ivanova et al., 2004; Jones, 1975; McBride et al., 1993; Sneath, 1960), though this is likely to change given the clinical significance of species such as *Brevibacterium casei* (Brazzola et al., 2000; Funke et al., 1997). Members of this taxon tend to be resistant to β-lactams, ciprofloxacin, clindamycin, and erythromycin and sensitive to gentamicin, rifampin, and tetracycline (Funke et al., 1996). Pitcher and Noble (1978) noted that nearly 90% of methanethiol-producing skin brevibacteria isolated from the feet of patients infected with *Trichophyton* species were resistant to penicillin. The antibiotic sensitivity profiles of individual *Brevibacterium* species are cited in the species descriptions.

Bacteriocins and antimicrobials. Several bacteriocins and antimicrobials are produced by *Brevibacterium linens* (Kato et al., 1984, 1991). These include Linocin A which shows inhibition to some other members of this species but not to other *Brevibacterium* species or to *Corynebacterium*, *Listeria*, and *Micrococcus* species (Valdes-Stauber and Scherer, 1994). Further, Linenscin OC2 from another *Brevibacterium linens* strain inhibits food borne pathogens including *Listeria monocytogenes* and *Staphylococcus aureus*. In addition, *Brevibacterium linens* strains isolated from brine used to salt red-smear cheeses produce an antimicrobial agent active against *Listeria* species (Martin et al., 1995).

Clinical significance. Members of the genus *Brevibacterium*, notably *Brevibacterium casei*, have quite recently been associated with human infections (Collins, 2006; Funke et al., 1997; McCaughey and Damani, 1991; Pitcher and Malnick, 1984). They have been implicated as agents of continuous ambulatory peritoneal dialysis (Antoniou et al., 1997; Gruner et al., 1993; Hummel et al., 1996; Wauters et al., 2000), corneal ulcers (Ghosheh et al., 2007), endocarditis (Dass et al., 2002), osteomyelitis (Neumeister et al., 1993), peritonitis (Cannon et al., 2005), septicemia (Carlotti et al., 1993; Kaukoranta-Tolvanen et al., 1995; Lina et al., 1994; Lipsky et al., 1982; Reinert et al., 1995; Ulrich et al., 2006), and sepsis in AIDS patients (Brazzola et al., 2000; Janda et al., 2003). In addition, *Brevibacterium luteolum* has been isolated from an ear discharge (Wauters et al., 2003), *Brevibacterium mcbrellneri* from infected genital hair of patients with white piedra in association with *Trichosporon beigelli* (McBride et al., 1993), *Brevibacterium massiliense* from an ankle discharge (Roux and Raoult, 2009), *Brevibacterium otitidis* from an ear infection (Pascual et al., 1996a), and *Brevibacterium paucivorans* from clinical samples (Wauters et al., 2001).

Ecology. Brevibacteria have been isolated from numerous habitats, notably ones with a high salt concentration. Most species have been derived either from dairy milk products, human skin, or clinical material. The usual habitat of *Brevibacterium linens* is the exterior of surface-ripened cheeses such as Limburger (Brennan et al., 2002), but it also occurs on cheeses such as Brick, Camembert, and Roquefort (El-Erian, 1969; Mulder et al., 1966). This organism is considered to be responsible for the surface color of red-smear cheeses and also, in part, by its proteolytic activity, to the ripening of such cheeses (Brennan et al., 2002). It is for this latter reason that *Brevibacterium linens* is often inoculated onto the surface of smear cheeses during the early stages of ripening, either as a commercial preparation or as the so-called "old-young" smearing method whereby young cheeses are washed with a brine suspension of microorganisms from the surface of mature cheese.

Strains now classified as *Brevibacterium casei* (Collins et al., 1983a) have been isolated from cheese curd, milk, and cheddar cheese, though the primary habitat of this organism is considered to be the human skin (Sharpe et al., 1976). *Brevibacterium epidermidis* is also thought to be part of the resident flora of human skin (Collins et al., 1983a; Pitcher and Noble, 1978). Other *Brevibacterium* species isolated from human material include *Brevibacterium luteolum* (corrig. Wauters et al., 2003), *Brevibacterium mcbrellneri* (McBride et al., 1993), *Brevibacterium otitidis* (Pascual et al., 1996a), and *Brevibacterium paucivorans* (Wauters et al., 2004b).

Brevibacteria have been recovered from marine habitats, as seen by the isolation of *Brevibacterium celere* from the degraded thallus of the brown alga *Fucus evanescens* (Ivanova et al., 2004), *Brevibacterium marinum* from sea water (Lee, 2008), *Brevibacterium oceani* from deep-sea sediment, and *Brevibacterium samyangense* from beach sand (Lee, 2006). Additional species have been isolated from more unusual sources such as *Brevibacterium album* from saline soil (Tang et al., 2008), *Brevibacterium salitolerans* from a hypersaline lake sediment sample (Guan et al., 2010), *Brevibacterium picturae* from a damaged mural painting (Heyrman et al., 2004), *Brevibacterium pityocampae* from healthy larvae of the moth, *Thaumelopoea pityocampae*, a pest of *Pinus* species in Mediterranean countries, including Turkey (Kati et al., 2010), and *Brevibacterium sandarakinum* from an indoor wall colonized by fungi (Kämpfer et al., 2010).

Enrichment and isolation procedures

Brevibacteria can be isolated on nutrient media based on glucose, peptone, and yeast extract, as exemplified by trypone soy agar supplemented with 4% (w/v) NaCl (TSAS; [Oxoid] 17 g; peptone, 3 g; NaCl, 9 g; K_2HPO_4, 2.5 g; glucose, 2.5 g; agar, 12 g; pH is adjusted to 7.0. The medium is sterilized at 121°C for 15 min). Isolation of the organisms is usually achieved by the use of such media supplemented with cheese, milk, and an elevated concentration of NaCl or sea water, as appropriate, depending on the environmental sample. Inoculated plates should be incubated at 20–25°C for 3–7 d, though temperatures of 30–37°C are better for the isolation of skin brevibacteria. It is important when isolating *Brevibacterium linens* that plates are exposed to light during some period of active growth to enhance pigment formation (Crombach, 1974; Mulder et al., 1966). A convenient practice is to incubate plates at 25°C until small colonies are evident and then to expose plates to light on the laboratory bench for the rest of the incubation period (Jones and Keddie, 1986).

Since isolation media are non-selective for brevibacteria, it is necessary to randomly select pigmented and nonpigmented colony types to establish whether cells have a coryneform morphology. When identification is limited to a consideration of isolates showing a rod–coccus growth cycle care must be taken to distinguish brevibacteria from organisms such as arthrobacters and rhodococci. Tests for this purpose are available (see section on differentiating the genus *Brevibacterium* from other genera).

Isolation from cheese. Samples of cheese or cheese curd are homogenized in 2% (w/v) trisodium citrate supplemented with NaCl (El-Erian, 1969). This medium is based on Tryptone

Soy Broth (Oxoid) though similar products are available from other sources such as BBL and Difco. Colonies growing on the isolation plates are examined as described above.

Sharpe et al. (1976) isolated brevibacteria from various dairy products by direct plating onto a medium containing 30% (w/v) skim milk and 2% (w/v) agar. All isolates were tested for the production of methanethiol from L-methionine (see *Procedures for testing for special characteristics*, below) and then examined for a coryneform morphology.

A medium which has been reported to be particularly suitable for the isolation of *Brevibacterium linens* from cheese is that of Albert et al. (1944). On this medium, which contains ripened cheese, *Brevibacterium linens* is reputed to give good pigment production in 5–7 d at 21°C or at room temperature, especially when plates are incubated in an oxygen-enriched atmosphere (Keddie and Jones., 1981).

Isolation from skin. Swabs moistened in physiological saline are rubbed firmly over the appropriate skin area and then streaked onto TSAS agar or Blood Agar Base no. 2 (Difco). After incubation at 30°C for 5–7 d colonies are randomly selected and examined for coryneform morphology. Further identification tests are then carried out.

Isolation from other sources. *Brevibacterium marinum* and *Brevibacterium samyangense* were isolated from sea water and sediment samples, respectively, using starch casein agar (Küster and Williams, 1964) prepared using 60% natural sea water (Lee, 2006, 2008). Similarly, *Brevibacterium oceani* was isolated by plating out a sediment sample suspended in 2% (w/v) NaCl onto yeast extract–peptone plates (Bhadra et al., 2008) and *Brevibacterium album* was isolated by inoculating a saline soil suspension onto glycerol-asparagine agar (Tang et al., 2008). Similarly, *Brevibacterium picturae* strains were isolated on R2A agar (Difco) supplemented with 1% (w/v) NaCl and on tryptic soy agar supplemented with 10% (w/v) NaCl, *Brevibacterium pityocampae* by inoculating suspensions of the contents of surface-sterilized insect larvae onto nutrient agar (Kati et al., 2010), and *Brevibacterium sandarakinum* by enriching a sample taken from a wall colonized by fungi in a 10 ml 0.9 (w/v) NaCl solution containing 0.01% (w/v) Tween 80 and plating dilutions onto M79 agar (Kämpfer et al., 2010).

Maintenance procedures

Brevibacteria may be preserved for some months by stab inoculation in nutrient agar (Oxoid) or similar media in screw-capped containers. After overnight incubation with the caps loose at 25 or 30°C, the caps should be screwed tightly to prevent evaporation. The containers may be stored at room temperature (~20°C), or better at ~4°C in the dark. Cultures may be preserved for longer periods (at least 7 years) by freezing in glass beads at −70°C (Feltham et al., 1978) or by lyophilization.

Procedures for testing for special characters

Presence of rod–coccus cycle. This may be demonstrated by using the methods described by Cure and Keddie (1973).

Cell-wall composition. Satisfactory results may be obtained with one of the methods described by Bousfield et al. (1985).

Detection of mycolic acids. This may be achieved by whole-organism methanolysis as described by Minnikin et al. (1984).

Polar lipid patterns. These may be determined by two dimensional TLC analysis of free lipid extracts (Collins et al., 1983a).

Test for the production of methanethiol. Sharpe et al. (1978) recommended the DTNB method of Laakso (1976) because it is more rapid and, in their experience, much more sensitive than the Conway diffusion method (Sharpe et al., 1978).

Organisms grown on nutrient agar slopes are suspended (to give an E_{580} of 10) in 0.05 M Tris/HCl buffer at pH 8.0; 1 ml samples are then incubated in rubber-stoppered test tubes with 12.5 mM L-methionine and 0.25 mM 5.5-dithiols (2-nitrobenzoic acid) (DTNB) in a total volume of 5 ml for 2 h at 30°C. Methanethiol production is indicated by the development of a yellow color in the test incubations. Positive tests are discernable by eye, but weak methanethiol producers may be confirmed colorimetrically at E_{420} after centrifugation of the bacterial growth. Controls (a) without cell suspensions and (b) without L-methionine should be incubated.

In addition, Pitcher and Malnick (1984) described a rapid method for the detection of methanethiol.

Differentiation of the genus *Brevibacterium* from other genera

16S rRNA gene sequencing is currently the most effective way of distinguishing brevibacteria from other actinomycetes, notably from those which show a rod–coccus growth cycle and contain *meso*-A_2pm in the wall peptidoglycan. Morphologically, members of the genus can be confused with *Corynebacterium*, *Dietzia*, *Gordonia*, *Rhodococcus*, and *Williamsia* strains but can be readily distinguished from the latter as they have fatty acids rich in iso- and anteiso-methyl branched components but lack mycolic acids and phosphatidylinositol dimannosides (Collins et al., 1980, 1983a; Goodfellow and Maldonado, 2006). Similarly, brevibacteria can be distinguished from arthrobacters and cellulomonads as they contain *meso*-A_2pm and not lysine or ornithine in the wall peptidoglycan (Collins, 2006). Bousfield et al. (1983) suggested that computer-assisted interpretation of fatty acid data combined with morphological examination may be sufficient to identify strains as members of the genera *Brevibacterium*, *Arthrobacter*, *Cellulomonas*, *Corynebacterium*, *Kurthia*, or *Oerskovia*.

Taxonomic comments

The genus *Brevibacterium* was proposed by Breed (1953a) to accommodate several Gram-stain-positive, asporogenous, nonbranching rod-shaped bacteria which had previously been classified in the genus *Bacterium*; *Brevibacterium linens* was designated the type species. The genus was recognized in the 7th edition of the *Manual* where it was classified with the genus *Kurthia* in the family *Brevibacteriaceae*. At that time, the genus *Brevibacterium* contained 23 species which were described as typically short, unbranched rods that were usually nonmotile; no mention was made of a coryneform morphology.

It was subsequently shown that *Brevibacterium linens* had a coryneform morphology and that it exhibited a rod–coccus growth cycle similar to that seen in *Arthrobacter globiformis* (Mulder and Antheumisse, 1963; Schefferle, 1966). In some earlier numerical taxonomic studies, it was even proposed that *Brevibacterium linens* should be transferred to the genus *Arthrobacter* as *Arthrobacter linens* (Bousfield, 1972; da Silva and Holt, 1965;

Davis and Newton, 1969). However, Fiedler et al. (1970) showed not only that the peptidoglycan in *Brevibacterium linens* was quite different from that in *Arthrobacter globiformis* and closely related species, but also that the 28 species named *Brevibacterium* which they examined were heterogeneous in peptidoglycan type. It was mainly for these reasons that the genus *Brevibacterium* was listed as *incertae sedis* in the 8th edition of the *Manual* (Rogosa and Keddie, 1974).

The heterogeneity of the genus was underpinned by chemotaxonomic (Keddie and Cure, 1978; Minnikin et al., 1978; Schleifer and Kandler, 1972) and numerical taxonomic (Jones, 1978; Seiler et al., 1977) studies and *Brevibacterium linens* was seen as a distinct taxon which could form the basis of a redefined genus (Jones, 1975; Keddie and Cure, 1977; Sharpe et al., 1978; Yamada and Komagata, 1972a). These and further studies led Collins et al. (1980) to redefine the genus *Brevibacterium* and at the same time to reclassify the organism previously designated "*Chromobacterium iodinum*" as *Brevibacterium iodinum*. Later, two groups of methanethiol-producing coryneform bacteria, one isolated from cheese and milk and the other from human skin, were classified as *Brevibacterium casei* and *Brevibacterium epidermidis* by Collins et al. (1983a). The methanethiol-producing organisms from cheese and milk were first isolated and well described by Sharpe et al. (1978, 1976, 1977) and those from skin by Pitcher and Noble (1978) and Sharpe et al. (1978). All of these investigators emphasized the similarity between these isolates and *Brevibacterium linens*, though at that time the genus *Brevibacterium* was *incertae sedis*.

The four *Brevibacterium* species mentioned above were recognized in the last edition of *Bergey's Manual of Systematic Bacteriology* by Jones and Keddie (1986) who also listed additional species that required further study so that they might be reclassified with confidence. In the meantime, new species have been assigned to the genus *Brevibacterium*, which now encompasses 24 validly published species forming a monophyletic branch in the 16S rRNA gene tree (Figure 148). In contrast, species previously associated with the genus have been transferred to other genera, as exemplified by the reclassification of *Brevibacterium ammoniagenes* Cooke and Keith 1927 and *Brevibacterium stationis* (ZoBell and Upham 1944) Breed 1953a as *Corynebacterium ammoniagenes* comb. nov. Collins 1987 and *Corynebacterium stationis* comb. nov. Bernard et al. 2010.

Differentiation of the species of the genus *Brevibacterium*

Brevibacterium species can be distinguished using a combination of phenotypic tests (Table 114) but not always with confidence, as a common set of tests are not yet available for the delineation of all species. *Brevibacterium linens* is most easily recognized by its ability to produce yellow to deep orange colonies (Jones et al., 1973; Mulder et al., 1966), though it needs to be remembered that DNA relatedness studies show that this taxon encompasses at least two species (Fiedler et al., 1981). The color reaction of *Brevibacterium linens* illicited by various chemicals has been used to distinguish members of this taxon (Grecz and Dack, 1961), but this test is not exclusively selective (Jones et al., 1973). The production of distinct purple extracellular crystals of iodinin by *Brevibacterium iodinum* is diagnostic for this organism (Clemo and Daglish, 1950; Davis, 1939; Sneath, 1960). In practice, closely related *Brevibacterium* species are distinguished using a combination of 16S rRNA gene sequence and phenotypic data (Kämpfer et al., 2010; Kati et al., 2010). Preliminary evidence suggests that *Brevibacterium* species can be separated on the basis of their MALDI-TOF mass spectra (Roux and Raoult, 2009).

List of species of the genus *Brevibacterium*

1. **Brevibacterium linens** (Wolff 1910) Breed 1953a, 13[AL] emend. Collins, Jones, Keddie and Sneath, 1980, 7 ("*Bacterium linens*" Wolff 1910)

li′nens. L. part. adj. *linens* spreading over, smearing.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which have a coryneform morphology and show a rod–coccus growth cycle when grown on complex media. Surface colonies on nutrient agar are small (0.1–0.2 mm in diameter) after 1–2 d, becoming larger (2.5 mm) on extended incubation. Mature colonies are shiny, convex, and have entire margins. On peptone–yeast extract media, an orange to orange-red pigment is produced. Pigment production by most strains, including the type strain, is light dependent. Pigmented growth gives characteristic color reactions with various acids and bases. Optimum growth temperature is 20–25°C; growth is generally poor or absent at 5°C and 37°C. Grows in the presence of 10% (w/v) NaCl. Acid is not produced from glucose or other sugars in peptone media. Gelatin is liquefied, hippurate hydrolyzed, and extracellular DNase produced. Weakly oxidase-positive. Methanethiol is produced from L-methionine. Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{17:0}$ anteiso and $C_{15:0}$ anteiso.

Common on surface-ripened smear cheeses.

Source: harzer cheese.

DNA G+C content (mol%): 60–64 (T_m).

Type strain: ATCC 9172, CIP 101125, DSM 20425, HAMBI 2038, JCM 1327, NBRC 12142, NRRL B-4210, VKM Ac-2112.

Sequence accession no. (16S rRNA gene): X77451.

Additional comments: Brevibacterium linens has been shown to be heterogeneous on the basis of nutritional properties (Mulder et al., 1966), electrophoretic protein patterns (Foissy, 1974) and DNA–DNA relatedness studies (Fiedler et al., 1981). Fiedler and his colleagues showed that strains designated *Brevibacterium linens* in public and private culture collections fell into at least two distinct species.

2. **Brevibacterium album** Tang, Wang, Schumann, Stackebrandt, Lou, Jiang, Xu and Li 2008, 576[VP]

al′bum. L. neut. adj. *album* white.

Aerobic, Gram-stain-positive, motile actinomycete which forms rods (1.8 × 4.0–5.0 μm). Colonies are white, smooth, circular, opaque, and 1–2 mm in diameter after incubation for 2 d on gelatin-asparagine agar (ISP medium 5) supplemented with 5% (w/v) NaCl. Growth occurs at 28–45°C with an optimum of 37°C; pH range 6–8 with an optimum of 7.5. Grows in the presence of NaCl, 0–10% (w/v) with an optimum of 0–5%.

The following carbon sources are used for growth in Biolog GP2 microplates: D-alanine, β-cyclodextrin, *N*-acetyl-D-glucosamine, fructose 6-phosphate, L-fucose, D-gluconic acid, *myo*-inositol, lactulose, D-mannitol, L-mannose, methyl β-D-galactoside, methyl α-D-glucoside, D-malic acid, palatinose, putrescine, salicin, succinic acid, trehalose, turanose, L-alanyl glycine, Tween 80, and uridine 5′-monophosphate.

Positive for alkaline phosphatase, gelatin hydrolysis, pyrazinamidase, pyrrolidonyl arylamidase, and acid production from D-ribose (API CORYNE tests). In addition, it is positive for acid and alkaline phosphatase, α-chemotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase (API ZYM tests). Additional phenotypic characteristics are shown in Table 114.

Cell wall contains galactose. Major fatty acids are anteiso $C_{15:0}$, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso. The predominant isoprenologue is MK-8(H_2); also contains MK-6, MK-6(H_2), MK-7(H_2), MK-8, and MK-9(H_2). The major phospholipids are diphosphatidylgylcerol and phosphatidylglycerol.

Source: a saline soil collected in northwest China.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: YIM 90718, CCTCC AB 20612, DSM 18261, JCM 15617, KCTC 19173.

Sequence accession no. (16S rRNA gene): EF158852.

3. **Brevibacterium antiquum** Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2005, 1[VP] (Effective publication: Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2004, 181.)

an.ti′qu.um. L.neut. adj. *antiquum* ancient, old.

Aerobic, Gram-stain-positive, nonmotile actinomycete which is composed mainly of coccoid cells in old cultures. Colonies are white to orange, circular, and slightly convex. Orange pigment is produced in the light. Grows at 7°C, but not at 37°C; optimal growth is between 24–26°C. Grows in the presence of 18% (w/v) NaCl.

Gelatin is hydrolyzed, but esculin and starch are not. Oxidase-positive. The ability to hydrolyze urea and to produce H_2S is strain-specific. L-Arabinose (slowly), D-fructose, D-galactose (slowly), D-glucose, glycerol, D-mannose, and D-xylose are used as carbon sources in a mineral medium supplemented with 0.05% (w/v) yeast extract, but D-melibiose, melezitose, raffinose and sorbitol are not. Acid is produced from fructose, D-galactose, D-glucose, mannose, and sorbitol, but not from inositol, inulin, D-mannitol, melezitose, raffinose, sorbose, rhamnose, or trehalose. Pyrrolidonyl arylamidase-positive, but negative for β-galactosidase, β-glucuronidase, and *N*-acetyl-β-glucosaminidase (API Coryne tests). Methyl red and Voges–Proskauer tests are negative. Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, and predominant menaquinone is MK-8(H_2). Cell-wall teichoic acids contain glucose, glycerol, and mannitol.

Source: 1.8–3-million-year-old ancient permafrost sediments located on the Kolyma Lowland, East Siberia, Russia.

DNA G+C content (mol%): 60.1–64.3 (T_m).

Type strain: JCM 13317, LMG 22206, UCM Ac-411, VKM Ac-2118.

Sequence accession no. (16S rRNA gene): AY243344.

Additional comments: the specific epithet *antiquum* is a "Latin adjective in the neuter gender" not a "modern noun adjective" (*sic*) as cited in the publication by Gavrish et al. (2005). The culture collection accession number LMG 22206 was provided on request for validation (List Editor, 2005).

4. **Brevibacterium aurantiacum** Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2005, 1[VP] (Effective publication: Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2004, 181.)

au.ran.ti′a.cum. N.L. neut. adj. *aurantiacum* orange-colored.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which are mainly present as coccoid cells in older cultures. Colonies are orange, circular, slightly convex, and glistening. Grows at 7°C and optimally between 24–26°C. Grows in the presence of 15% (w/v) NaCl.

H_2S is produced. Does not hydrolyze esculin, starch, or urea. Production of acid from fructose and gelatin hydrolysis are strain-specific. Cellobiose, fructose, D-galactose, D-glucose, glycerol, D-mannose, and D-xylose are used as carbon sources in a mineral medium supplemented with 0.05% (w/v) yeast extract, but adonitol, L- and D-arabinose, D-arabitol, dulcitol, *meso*-erythritol, L-fucose, inositol, lactose, D-melibiose, raffinose, salicin, sorbitol, and trehalose are not. Acid is produced from galactose, D-glucose, mannose, and salicin, but not from inositol, inulin, D-mannitol, melezitose, raffinose, sorbose, sorbitol, or trehalose. Alkaline phosphatase-positive, but negative for pyrrolidonyl arylamidase, β-glucuronidase, β-galactosidase, and *N*-acetyl-β-glucosaminidase (API Coryne system). Additional phenotypic characteristics are shown in Table 114.

Major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso, and the predominant menaquinone MK-8(H_2). Contains glycerol teichoic acids.

Source: cheese.

DNA G+C content (mol%): 60.1–64.3 (T_m).

Type strain: ATCC 9175, JCM 2590, LMG 22546, NCIMB 8546), VKM Ac-2111.

Sequence accession no. (16S rRNA gene): X76566.

Additional comments: the culture collection accession number LMG 22546 was provided on request for validation (List Editor, 2005).

5. **Brevibacterium avium** Pascual and Collins 1999, 1529[VP]

a′vi.um. L. n. *avis* a bird; L. gen. pl. n. *avium* of birds.

Aerobic, Gram-stain-positive, non-acid-fast, nonmotile actinomycetes which have a coryneform morphology. Colonies are convex, with entire margins and are round, smooth, grayish-white and butyrous. Grows well at 22 and 30°C and optimally at 37°C.

Tyrosine is decomposed and extracellular DNase produced. Gelatin and xanthine are degraded, but not esculin, starch or urea. L-Arabinose, D-arabitol, D-fructose, galactose, D-glucose, glycerol, D-mannose, and mannitol are used as sole carbon sources, but not adonitol, amygdalin, L-arabitol, arbutin, cellobiose, dulcitol, erythritol, D-fucose, L-fucose, β-gentiobiose, 2-ketogluconate, 5-ketogluconate, *N*-acetylglucosamine, methyl-α-D-glucoside, glycogen, inositol, inulin, lactose, D-lyxose, maltose, methyl α-D-mannoside, melezitose, melibiose, D-raffinose, rhamnose, ribose, salicin, sorbitol, L-sorbose, starch, sucrose, D-tagatose, trehalose, D-turanose, xylitol, D-xylose, or methyl β-xyloside. Does not produce acid from glucose, maltose, mannitol, sucrose, or xylose. Positive for alkaline and acid phosphatase, esterase (C4), ester lipase (C8), leucine arylamidase, and phosphoamidase, but negative for α-chymotrypsin, α-fucosidase, β-fucosidase, α-galactosidase, β-glucuronidase, α-mannosidase, *N*-acetyl-β-glucosaminidase, trypsin, and valine arylamidase (API ZYM tests). Additional phenotypic characteristics are shown in Table 114.

Galactose, but not arabinose, is present in the cell wall.

Source: bumble-foot-like manifestations of poultry.

DNA G+C content (mol%): not determined.

Type strain: CCUG 43455, CIP 106532, JCM 11680, NCIMB 703055.

Sequence accession no. (16S rRNA gene): Y17962.

6. **Brevibacterium casei** Collins, Farrow, Goodfellow and Minnikin 1983b, 896[VP] (Effective publication: Collins, Farrow, Goodfellow and Minnikin 1983a, 393.)

ca′se.i. L. n. *caseus* cheese; L. gen. n. *casei* of cheese.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which have a coryneform morphology. Gray-white colonies are produced on nutrient agar. A brown, water soluble pigment is formed on milk agar. Grows well at 40°C, and optimally between 30–37°C. Survives heating in nutrient broth (Oxoid) at 60°C for 30 min. Tolerant to 15% (w/v) NaCl.

Gelatin is hydrolyzed and extracellular DNase produced. Reduction of nitrate is variable. Weak acid production from glucose has been reported using the method of Hugh and Leifson (1953). Glucose, sucrose, acetate, and lactate are used as sole carbon sources. Additional phenotypic characteristics are shown in Table 114.

DNA–DNA relatedness values between the type strain and representatives of related species are as follows: *Brevibacterium epidermidis* (22–23%), *Brevibacterium iodinum* (14% with type strain), and *Brevibacterium linens* (19% with type strain).

Source: cheddar cheese, cheese curd, and raw milk.

DNA G+C content (mol%): 66–67 (T_m).

Type strain: ATCC 35515, CCM 4100, BCRC 12214, CCUG 29001, CIP 102111, DSM 20657, IMET 10997, JCM 2594, KCTC 3082, KCTC 3085, NBRC 14812, NCIMB 702048, VKM Ac-2114.

Sequence accession no. (16S rRNA gene): AJ251418, X76564.

Additional comments: Brevibacterium casei Collins et al., (1983a) was previously known as CDC coryneform groups B-1 and B-3. The name *Brevibacterium casei* (effective publication: Collins et al. 1983a), type strain CMD1 = NCIMB 702048 (formerly NCDO 2048) appears on validation lists 12 and 13. The date of valid publication of the name is the first citation, namely the one in validation list 12 (Euzéby and Kudo, 2001).

7. **Brevibacterium celere** Ivanova, Christen, Alexeeva, Zhukova, Gorshkova, Lysenko, Mikhailov and Nicolau 2004, 2110[VP]

ce′le.re. L. neut. adj. *celere* rapid, indicating the rapid growth on nutrient media.

Aerobic, Gram-stain-positive, non-acid-fast, nonmotile actinomycetes which have a coryneform morphology. Colonies are circular, convex with entire margins, whitish yellow with a butyrous consistency. Growth occurs between 12–42°C, and from pH 5–10 with an optimum at 8.5–9.0. Tolerant to 15% (w/v) NaCl.

Alginate, gelatin, and laminarin are degraded but starch is not. Negative for urease production. The following car-

bon sources are used for growth in Biolog GP2 microplates: acetic acid, *cis*-aconitic acid, alaninamide, γ-aminobutyric acid, bromosuccinic acid, D-and L-alamine, D-and L-carnitine, D-gluconic acid, α-D-glucose, D- and L-lactic acid, D-trehalose, dextrin, formic acid, glycerol, glycyl L-glutamic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, *p*-hydroxyphenylacetic acid, hydroxyproline, α-ketobutyric acid, L-alanyl glycine, L-asparagine, L-aspartic acid, L-fucose, L-glutamic acid, L-histidine, L-leucine, L-ornithine, L-phenylalanine, L-proline, L-pyroglutamic acid, L-serine, maltose, methylpyruvate, monomethyl succinate, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, phenylethylamine, propionic acid, putrescine, quinic acid, sebacic acid, succinic acid, sucrose, turanose, Tween 40, Tween 80, and urocanic acid. Does not form acid from galactose, glucose, lactose, maltose, sorbose, or xylose.

Susceptible to (μg/ml): carbenicillin (10) and oleandomycin (30), but resistant to: ampicillin (10), benzylpenicillin (10), gentamicin (10), kanamycin (30), lincomycin (15), neomycin (30), streptomycin (30), and polymyxin B (25). Additional phenotypic characteristics are shown in Table 114.

Major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: the brown alga *Fucus evanescens*.

DNA G+C content (mol%): 61.4 (T_m).

Type strain: ATCC BAA-809, DSM 15453, JCM 13521, KMM 3637.

Sequence accession no. (16S rRNA gene): AY228463.

8. **Brevibacterium epidermidis** Collins, Farrow, Goodfellow and Minnikin 1983b, 896[VP] (Effective publication: Collins, Farrow, Goodfellow and Minnikin 1983a, 393.)

e.pi.der′mi.dis. Gr. n. *epidermida* the outer skin; N.L. gen. n. *epidermidis* of the epidermis.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which have a coryneform morphology. Gray-white colonies are formed on nutrient agar. Grows optimally between 30–37°C; some strains grow at 40°C. Grows in presence of 15% (w/v) NaCl.

Gelatin is hydrolyzed and extracellular DNase is produced. Nitrate reduction is strain-dependent. Acetate and lactate are used as sole carbon sources. Acid is not produced from glucose in peptone media. Additional phenotypic characteristics are shown in Table 114.

DNA–DNA relatedness values between the type strain and representatives of related species are as follows: *Brevibacterium casei* (31–44%), *Brevibacterium iodinum* (33% with type strain), and *Brevibacterium linens* (14% with type strain).

Source: human skin.

DNA G+C content (mol%): 63.5 (T_m).

Type strain: ATCC 35514, BCRC 2215, CCM 4098, CCUG 30540, CIP 102110, DSM 20660, IMET 10998, JCM 2593, KCTC 3090, NBRC 14811, NCIMB 702286, NCTC 12997, VKM Ac-2108.

Sequence accession no. (16S rRNA gene): X76565.

Additional comments: the species name *Brevibacterium epidermidis* [effective publication: Collins et al. 1983a; type strain: strain D731 = NCIMB 702286 formerly NCDO 2286] appears on Validation Lists 12 and 13. The date of the valid publication of this name is the first citation, namely the one cited in Validation List 12 (Euzéby and Kudo, 2001).

9. **Brevibacterium iodinum** (*ex* Davis 1939) Collins, Jones, Keddie and Sneath 1981, 216[VP] (Effective publication Collins, Jones, Keddie and Sneath 1980, 7.)

i.o.di′num. N.L. neut. n. *iodinum* iodine.

Aerobic, nonmotile actinomycetes which have a rod–coccus growth cycle. Cells frequently appear Gram-stain-negative. In very young cultures (approx. 8 h), cells frequently stain one-half Gram-positive, the other half Gram-negative. Colonies on nutrient agar are whitish-gray and smooth, convex with entire margin, and shiny. Blue to purple extracellular crystals of iodinin are produced on a variety of media. Iodinin production is not influenced by light. Grows between 20–37°C, optimally between 25–30°C, but does not grow below 12°C.

Catalase-positive. Gelatin is hydrolyzed. DNase is produced. Hippurate is not hydrolyzed. H_2S is produced from cysteine but not from sodium thiosulfate. Does not produce acid from glucose or other sugars in peptone based media. Citrate is utilized. Additional phenotypic characteristics are shown in Table 114.

Major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: milk.

DNA G+C content (mol%): 60–63 (T_m).

Type strain: ATCC 49514, BCRC 12216, DSM 20626, IMET 10995, JCM 2591, KCTC 3083, NBRC 15230, NCIMB 700613, NCTC 12955, NRRL B-1717, VKM Ac-2106.

Sequence accession no. (16S rRNA gene): X76567, X83813.

10. **Brevibacterium luteolum** corrig. Wauters, Avesani, Laffineur, Charlier, Janssens, Van Bosterhaut and Delmée 2003, 1324[VP]

lu.te′o.lum. L. neut. adj. *luteolum* yellowish, because colonies exhibit a yellow pigment.

Aerobic, Gram-stain-positive rods (2–3 μm long) which show a diphtheroid morphology, but not a rod–coccus growth cycle. Colonies are smooth, yellowish, and approximately 1–2 mm in diameter after incubation for 2 d at 37°C. Grows optimally between 30 and 37°C; some strains grow at 20°C. Grows in the presence of 10% (w/v) NaCl.

Gelatin is degraded, but esculin, tyrosine, and xanthine are not. Ethylene glycol is acidified. γ-Aminobutyric acid is utilized and alkalinized on Simmon's agar base. Phenylacetate is acidified and methanethiol produced from L-methionine. Pyrrolidonyl peptidase-positive. *N*-Acetyl-β-D-glucosaminidase is positive when the nitrophenyl compound is used as substrate (Rosco). Positive for lipase esterase (C8), leucine arylamidase, and phosphoamidase, and acid and alkaline phosphatase variable (negative for the type strain) (API ZYM tests). Additional phenotypic characteristics are shown in Table 114.

Main fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. Isolated from clinical and environmental samples.

Source: peritoneal fluid of a patient undergoing dialysis.

DNA G+C content (mol%): 68.8 (T_m).

Type strain: CF87, CCUG 46604, DSM 15022, JCM 12367.

Sequence accession no. (16S rRNA gene): AJ488509.

Additional comments: Wauters et al. (2003) proposed the specific epithet *lutescens*. However, *lutescens* (L. part. adj. from L. v. *lutesco*) means becoming muddy, not yellowish as cited in the paper by Wauters et al. Consequently, this

specific epithet was corrected on notification with the author's agreement (Euzéby, 2004).

11. **Brevibacterium marinum** Lee 2008, 503[VP]

ma.ri'num. L. neut. adj. *marinum* of the sea, marine.

Aerobic, Gram-stain-positive, nonmotile actinomycete which forms long rods (1.5–2.4 × 0.6–0.9 μm) at the exponential growth phase; as the cultures age these elements fragment into short rods (0.5–0.6 × 0.7–1.0 μm) which occasionally occur singly but more often, in pairs or in chains. V-forms are observed. Colonies are translucent, convex, smooth, and circular with entire margins. Pigment production is variable depending on the culture conditions. In the dark colonies are white; in the light, they are bright yellow. Grows from 10–30°C, optimally at 30°C; does not grow at 4 or 37°C. Growth occurs in the pH range 5–12. Tolerant to 10% (w/v) NaCl.

Hypoxanthine is degraded, but not DNA, gelatin, starch, cellulose, tyrosine, or xanthine. Positive for nitrate reduction, β-galactosidase, and urease, but negative for alkaline phosphatase, β-glucosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, and pyrrolidonyl arylmidase (API Coryne tests). Esterase (C4) and esterase lipase (C8) are weakly positive, but acid phosphatase, alkaline phosphatase, α-chemotrypsin, cysteine arylamidase, galactosidase, β-glucosidase, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase are negative (API ZYM tests). Does not produce acid from D-glucose, D-lactose, maltose, D-mannitol, D-ribose, sucrose, or D-xylose. Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, and $C_{18:0}$. The predominant menaquinone is MK-8(H_2), and the major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidyl methyl inositol; an unknown phospholipid is present as a minor component.

Source: seawater from Hwasun Beach in Jeju, Republic of Korea.

DNA G+C content (mol%): 71.4 (HPLC).

Type strain: HFW-26, DSM 18964, JBRI 2001, JCM 15618, KCTC 19221.

Sequence accession no. (16S rRNA gene): AM421807.

12. **Brevibacterium massiliense** Roux and Raoult 2009, 1962[VP]

mas.si.li.en'se. L. neut. adj. *massiliense* of Massilia, the old Roman name for Marseille, where the type strain was isolated.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which form short, irregular straight rods (0.4–1.4 × 0.3–0.5 μm). Colonies are beige, shiny, smooth, circular, and 0.2 mm in diameter after growth for 24 h in 5% CO_2 on sheep blood agar. Grows between 25–45°C, optimally between 30–37°C. Good growth in the presence of 1–10% (w/v) NaCl.

Does not hydrolyze gelatin. Positive for esterase (C4) and leucine arylamidase, but negative for alkaline phosphatase, α-fucosidase, β-glucosidase, β-glucuronidase, α-mannosidase, *N*-acetyl-β-glucosaminidase, and naphthol-AS-BI-phosphohydrolase (API ZYM tests). Positive for alanine arylamidase, arginine arylamidase, glycine arylamidase, leucine arylamidase, leucyl-glycine arylamidase, phenylalanine arylamidase, proline arylamidase, serine arylamidase, and tyrosine arylamidase (API 32A tests).

The following sole carbon sources are used for growth in Biolog GP2 microplates: acetic acid, 2,3-butanediol, D-alanine, glycyl L-glutamic acid, α-hydroxybutyric acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketovaleric acid, L-alaninamide, L-alanine, L-alanyl glycine, L-asparagine, L-glutamic acid, L-lactic acid, L-serine, *N*-acetyl-L-glutamic acid, propionic acid, pyruvic acid, pyruvic acid methyl ester, succinic acid monomethyl ester, Tween 40, and Tween 80. Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso.

Source: a human ankle discharge sample.

DNA G+C content (mol%): not determined.

Type strain: 5401308, CCUG 53855, CIP 109422, CSUR P26.

Sequence accession no. (16S rRNA gene): EU868814.

13. **Brevibacterium mcbrellneri** McBride, Ellner, Black, Clarridge and Wolf 1994, 852[VP] (Effective publication: McBride, Ellner, Black, Clarridge and Wolf 1993, 260.)

mc.brell'ne.ri. N.L. masc. gen. n. *mcbrellneri* of McBrEllner, named for two of the authors (M.E. McBride and K.M. Ellner) of the publication describing its isolation and characteristics.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which show a rod–coccus growth cycle. Colonies are whitish-beige, dry, and friable. Grows at 37°C, but not at 20°C. Tolerates 6.5% (w/v) NaCl but not higher concentrations of salt.

DNA and gelatin are hydrolyzed. Xanthine degradation is variable. Pyrrolidone peptidase is negative. Produces methanethiol from L-methionine. Ribose is used as a sole carbon source, but mannose is not. Acid is produced from 2,3-butylene glycol.

Sensitive (μg/ml) to ampicillin (10), cephalothin, methoprim sulfate (24), penicillin (2), and vancomycin (15), but resistant to erythromycin (15), oxacillin (10), and tetracycline (30). Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ antieso and $C_{17:0}$ anteiso. Cell walls contain galactose, glucose, and xylose.

Source: infected genital hair of patients with white piedra.

DNA G+C content (mol%): 63.05 (T_m).

Type strain: E2cr, ATCC 49030, CCUG 37313, DSM 9583, JCM 11682.

Sequence accession no. (16S rRNA gene): X93594.

14. **Brevibacterium oceani** Bhadra, Raghukumar, Pindi and Shivaji 2008, 59[VP]

o.ce.a'ni. L. gen n. *oceani* of the ocean.

Aerobic, Gram-stain-positive, nonmotile, rod-shaped (2.0–3.0 × 1.0–1.2 μm) actinomycetes. Sticky, pale orange colonies (~1.5–2.0 mm in diameter) with entire margins are formed at 28°C on nutrient agar. Growth occurs between 10–35°C, but not at 5 or 37°C. pH for growth is between 5.2–9.5 with an optimum of 6.8.

L-Arginine, L-asparagine, L-lysine, malonate, L-proline, L-serine, and L-tyrosine are used as carbon sources, but adon-

itol, L-cystine, erythritol, D-glucuronate, and 2-oxoglutarate are not. Acid is produced from phenylacetate, but not from adonitol, D- and L-arabinose, D-cellobiose, dulcitol, fructose, D-galactose, glucose, inositol, lactose, maltose, D-mannitol, mannose, D-melibiose, D-raffinose, rhamnose, D-ribose, sucrose, trehalose, or D-xylose. Positive for lysine decarboxylase and ornithine decarboxylase, but negative for citrate utilization, esculin hydrolysis, β-galactosidase, H_2S production, indole production, methyl red and Voges–Proskauer tests, oxidase, and phenylalanine deamination.

Resistant to (μg/ml): chloramphenicol (25), nalidixic acid (15), and polymixin B (15), but sensitive to ampicillin (25), kanamycin (30), roxithromycin (30), streptomycin (25), and tetracycline (25). Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. The predominant menaquinone is MK-8(H_2), and the major polar lipids are diphosphatidylglycerol and phosphatidylglycerol.

Source: a 50–70 cm section of a deep-sea sediment core of 4.6 m length obtained from the Chagos Trench, Indian Ocean, at a water depth of 5904 m.

DNA G+C content (mol%): 59.8–60.2 (T_m).

Type strain: BBH7, IAM 15353, JCM 21798, LMG 23457.

Sequence accession no. (16S rRNA gene): AM158906.

15. **Brevibacterium otitidis** Pascual, Collins, Funke and Pitcher 1996b, 1189[VP] (Effective publication: Pascual, Collins, Funke and Pitcher 1996a, 121.)

o.ti′ti.dis. Gr. n. *ous, otos* ear; N.L. suff. *-itis, idis* suffix used in names of inflammations; N.L. gen. n. *otitidis* of inflammation of the ear.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which have a coryneform morphology. Colonies are whitish-yellowish and friable with a dry texture. Growth is observed at 37°C but not at 20°C.

Gelatin and xanthine are degraded. Positive for production of pyrrolidone peptidase. Additional phenotypic characteristics are shown in Table 114.

Source: a human ear infection.

DNA G+C content (mol%): not determined.

Type strain: A37/73, ATCC 700348, BBH7, CCUG 37257, CIP 10544, DSM 10718, JCM 11683, NCIMB 703053.

Sequence accession no. (16S rRNA gene): X93593.

16. **Brevibacterium paucivorans** Wauters, Charlier and Janssens Delmée 2001, 1706[VP]

pau.ci.vo′rans. L. adj. *paucus* little; L. v. *vorare* to eat; N.L. part. adj. *paucivorans* eating little, because few substrates are assimilated.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which form short, plump rods with a coryneform morphology. Colonies are grayish, glistening and smooth or sticky and approximately 2 mm in diameter after incubation for 2 d at 37°C on blood agar. Grows at 37°C, but not 20°C.

Carbohydrates are neither acidified nor assimilated. Gelatin is liquefied weakly and slowly. Does not hydrolyze esculin, or degrade tyrosine or xanthine. Ethylene glycol is acidified but 2,3-butylene glycol is not. Methanethiol is produced from L-methionine. Urea is hydrolyzed. Pyrrolidonyl peptidase is negative. Positive for leucine arylamidase and phosphoamidase; weakly positive for esterase lipase (C8), but negative for acid phosphatase, alkaline phosphatase, α-chymotrypsin, cystine arylamidase, esterase (C4), α-fucosidase, α-and β-glucosidase, α-mannosidase, *N*-acetyl-β-glucosaminidase, and valine arylamidase; some strains are positive for trypsin (API ZYM tests). Additional phenotypic characteristics are shown in Table 114.

The cell wall contains an excess of glutamic acid and glycine moieties that are not bound to the peptidoglycan. The cellular fatty acids are of the branched type with $C_{15:0}$ anteiso and $C_{17:0}$ anteiso as major components. Isolated from clinical material.

Source: blood.

DNA G+C content (mol%): 55.8 (T_m).

Type strain: CF62, CCUG 45688, DSM 13657, JCM 11567, LMG 19814.

Sequence accession no. (16S rRNA gene): AJ251463.

17. **Brevibacterium permense** Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2005, 1[VP] (Effective publication: Gavrish, Krauzova, Potekhina, Karasev, Plotnikova, Altyntseva, Korosteleva and Evtushenko 2004, 182.)

per.men′se. N.L. neut. adj. *permense* pertaining to Perm, a region of Russia.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which are mainly present as coccoid cells in older cultures. Colonies are white to orange, circular, slightly convex, and glistening. Orange pigment is produced in the light. Grows at 37°C; optimal temperature for growth is 24°C. Grows in the presence of 18% (w/v) NaCl.

Gelatin is hydrolyzed but esculin and urea are not. H_2S is produced. The methyl red and Voges–Proskauer tests are negative. Does not degrade starch. L-Arabinose, cellobiose, fructose, D-galactose, D-glucose, gluconate, glycerol, D-mannose, raffinose, salicin, trehalose, and D-xylose are used as carbon sources when prepared in a mineral medium supplemented with 0.05% (w/v) yeast extract, but D-arabinose, D-arabitol, adonitol, dulcitol, *meso*-erythritol, L-fucose, inositol, lactose, D-melibiose, and sorbitol are not. Acid is produced from D-galactose, D-glucose, fructose, mannose, salicin, and sorbitol, but not from inositol, inulin, D-mannitol, melezitose, raffinose, rhamnose, sorbose, or trehalose. Positive for alkaline phosphatase, but negative for pyrrolidonyl arylmidase, β-glucuronidase, β-galactosidase, and *N*-acetyl-β-glucosaminidase (API Coryne tests). Additional phenotypic characteristics are shown in Table 114. The major menaquinone is MK-8(H_2). Cell-wall teichoic acid contains glycerol, mannose, and mannitol.

Source: salt-contaminated soil samples collected in the Perm region of Russia.

DNA G+C content (mol%): 60.1–64.3 (T_m).

Type strain: JCM 13318, LMG 22207, UMC Ac-413, VKM Ac-2280.

Sequence accession no. (16S rRNA gene): AY243343.

Additional comments: the culture collection number was provided on request for validation (List Editor, 2005).

18. **Brevibacterium picturae** Heyrman, Verbeeren, Schumann, Devos, Swings and De Vos 2004, 1540[VP]

pic.tu′ra.e. L. gen. n. *picturae* of a painting.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which do not form a clear rod–coccus cycle on nutrient agar. Single coccoid cells (0.8 × 1.0 μm) are formed after growth for 6 and 16 h, single coccoid to oval cells after 24 h; after 72 h growth, cells are oval or short rods which occur singly or in pairs (1.0–1.5 × 4.0 μm). Colonies on nutrient agar are white, low-convex, slightly transparent to opaque, and circular with entire margins. Growth is variable at 37°C, optimal between 20–30°C, but does not grow at 10°C. The pH range for growth is 6–9, with an optimum at pH 7.0. Tolerant to 10% (w/v) NaCl.

Positive for alkaline phosphatase, urease, and gelatin hydrolysis, and negative for pyrrolidonyl arylamidase, β-glucuronidase, esculin, and fermentation of ribose, xylose, mannitol, and glycogen; variable for nitrate reduction, β-galactosidase, and acid production from glucose, lactose, maltose, and sucrose (API Coryne tests).

Weakly positive for esterase (C4), esterase lipase (C8), and naphthol-AS-BI-phosphohydrolase; variable for acid phosphatase and leucine arylamidase, and negative for α-chymotrypsin, cystine arylamidase, α-fucosidase, α-galactosidase, β-glucosidase, α-mannosidase, trypsin, and valine arylamidase (API ZYM tests). Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso. The predominant menaquinone is MK-8(H_2), and the major polar lipids are diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, an unknown glycolipid, and an unknown phospholipid.

Source: a mural painting discolored by microbial growth.

DNA G+C content (mol%): 63.3 (HPLC).

Type strain: DSM 16132, JCM 13319, LMG 22061.

Sequence accession no. (16S rRNA gene): AJ620364.

19. **Brevibacterium pityocampae** Katı, İnce, Demir and Demirbağ 2010, 315[VP]

pi.ty.o.cam′pae. L. fem. n. *pityocampa* a pine grub; L. fem. gen. n. *pityocampae* of a pine grub, referring to the isolation of the type strain from larvae of *Thaumetopoea pityocampa*.

Aerobic, Gram-stain-positive, nonmotile actinomycete which forms rods (1.0 × 0.5 μm). Colonies are yellow, circular, and convex with entire margins. Grows at 25–40°C, from pH 6.0–9.0, and optimally at pH 8.0. Grows in 0–10%, but not 15% (w/v) NaCl.

Arginine dihydrolase, β-galactosidase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase are not formed. Does not produce acetoin, hydrogen sulfide, or indole; gelatin is not degraded and citrate is not utilized. Does not produce acid from amygdalin, L-arabinose, D-glucose, inositol, D-mannitol, melibiose, L-rhamnose, D-sorbitol, or sucrose. Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

Source: healthy larvae of *Thaumetopoea pityocampa* from the Middle Black Sea region of Turkey.

DNA G+C content (mol%): 69.8 (HPLC).

Type strain: Tp12, DSM 21720, NCCB 100255.

Sequence accession no. (16S rRNA gene): EU484189.

20. **Brevibacterium ravenspurgense** Mages, Frodl, Bernard and Funke 2009, 1[VP] (Effective publication: Mages, Frodl, Bernard and Funke 2008, 2985.)

ra.vens.pur.gen′se. N.L. adj. *ravenspurgense* pertaining to Ravenspurgum, Latin name of the town of Ravensburg, Germany, where the type strain of this species was isolated.

Aerobic, Gram-stain-positive, nonmotile actinomycetes which show a coryneform morphology. Colonies are whitish-grayish, slightly convex, have a sticky consistency, and are up to 2 mm in diameter after incubation for 24 h at 35°C on Columbia SBA plates.

Positive for esterase (C4), esterase lipase (C8), leucine arylamidase, and naphthol-AS-BI-phosphohydrolase, but negative for acid phosphatase, α-chymotrypsin, α-fucosidase, α-galactosidase, β-galactosidase, gelatinase, *N*-acetyl-β-glucosaminidase, α-glucosidase, β-glucosidase, β-glucuronidase, lipase (C14), α-mannosidase, nitrate reductase, pyrrolidonyl arylamidase, urease, and valine arylamidase; variable for alkaline phosphatase and trypsin (API ZYM tests). Does not use carbohydrates in the system described by Funke and Carlotti (1994). Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$.

Source: the town of Ravensburg in Germany.

DNA G+C content (mol%): not determined.

Type strain: CCUG 56047, DSM 21258.

Sequence accession no. (16S rRNA gene): EU086793.

21. **Brevibacterium salitolerans** Guan, Zhau, Xiao, Liu, Xia, Zhang and Zhang 2010, 2993[VP]

sa.li.to.le′rans. L. n. *sal salis* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *salitolerans* salt-tolerating, originating from a saline habitat.

Aerobic, Gram-stain-positive, nonmotile actinomycete which forms rods (1.3–1.8 × 0.6–1.0 μm) but does not show a rod–coccus growth cycle. Colonies on glycerol-asparagine agar (ISP 5 medium) supplemented with 2% (w/v) NaCl, 1% (w/v) KCl, and 0.5% (w/v) $MgCl_2$ are 2.0–3.5 mm in diameter, smooth, circular, and whitish-yellow after 5 d. Colonial pigmentation is always whitish-yellow in both the dark and light. Grows from 15–50°C, optimally between 28 and 40°C, but does not grow at 10°C or 52°C. Grows from pH 5.0–9.0, optimally at pH 7.0–7.5. Tolerant up to 18% (w/v) NaCl, but grows optimally in the presence of 3.8% (w/v) NaCl.

Degrades gelatin, but not cellulose, starch, or Tweens 20, 40, or 80. Positive for alkaline phosphatase, gelatin hydrolysis, β-glucosidase, pyrazinamidase, pyrrolidonyl arylamidase, and acid production from D-ribose (API CORYNE tests). Does not coagulate or peptonize milk or produce H_2S. Methyl red and Voges–Proskauer tests are negative.

The following sole carbon sources are used for growth in Biolog GP2 microplates: acetic acid, *N*-acetyl-L-glutamic acid, adenosine, L-alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, 2,3-butanediol, α-cyclodextrin, 2′-deoxy adenosine, dextrin, L-fucose, D-gluconic acid, L-glutamic acid, glycogen, glycyl L-glutamic acid, α-, β- and γ-hydroxybutyric acid, inosine, α-ketovaleric acid, lactamide, L-lactic acid, D-lactic acid methyl ester, D-malic acid, L-malic acid, methyl pyruvate, monomethyl succinate, propionic

acid, pyruvic acid, L-serine, succinamic acid, succinic acid, thymidine, Tween 40, and Tween 80. Additional phenotypic characteristics are shown in Table 114.

The DNA–DNA relatedness value between the type strain and the corresponding strain of *Brevibacterium album* is 41.3%. The major fatty acids are $C_{17:0}$ anteiso and $C_{15:0}$ anteiso. The predominant menaquinone is MK-8(H_2), but smaller amounts of MK-6(H_2), MK-7, MK-7(H_2), and MK-8 are also present. The major polar lipids are diphosphatidylglycerol and phosphatidylglycerol.

Source: a hypersaline sediment sample collected from Lop Nur salt lake in Xinjiang Province, north-west China.

DNA G+C content (mol%): 69 (HPLC).

Type strain: TRM 415, CCTCC AB 208328, JCM 15900, KCTC 19616.

Sequence accession no. (16S rRNA gene): GU117109.

22. **Brevibacterium samyangense** Lee 2006, 1891[VP]

sam.yang.en′se. N.L. neut. adj. *samyangense* of Samyang Beach, Jeju, Republic of Korea, from where the type strain was isolated.

Aerobic, Gram-stain-positive, motile actinomycetes which show an apparent rod–coccus growth cycle on yeast extract-sea water agar; single or paired coccoid cells are seen after 6 h together with rare short rods; after 12–16 h most cells are irregular, slender rods, arranged in V-forms, while coccoid cells occur singly, in pairs, or in chains after 24–72 h. Colonies are opaque, convex, circular, and bright yellow in color with an entire edge. Grows from 10–45°C, but not at 4 or 55°C, from pH 6.1–10.1, and in the presence of 15% (w/v) NaCl.

Degrades D- and L-tyrosine, but not xanthine. The following sole carbon sources are used for growth in Biolog GP2 microplates: acetic acid, *N*-acetyl-L-glutamic acid, *N*-acetyl-D-glucosamine, *N*-acetyl-β-mannosamine, adenosine, adenosine 5′-monophosphate, L-alaninamide, D- and L-alanine, L-alanylglycine, amygdalin, L-arabinose, arabitol, L-asparagine, D-cellobiose, β-cyclodextrin, 2-deoxyadenosine, dextrin, D-fructose, L-fucose, D-galactose, D-galacturonic acid, α-D-glucose, D-glucose 6-phosphate, α-D-glucoside 1-phosphate, L-glutamic acid, DL-α-glycerol phosphate, glycogen, glycyl L-glutamic acid, *p*-hydroxyphenylacetic acid, α-, β-, and γ-hydroxybutyric acids, inosine, *myo*-inositol, inulin, α-ketoglutaric acid, lactamide, L-lactic acid, D-lactic acid methyl ester, α-D-lactose, lactulose, L-malic acid, maltose, maltotriose, mannan, D-mannose, D-melezitose, D-melibiose, methyl ethyl α-D-mannoside, methyl α-D-galactoside, 3-methyl D-glucoside, methyl β-D-glucoside, methyl pyruvate, monomethyl succinate, palatinose, propionic acid, D-psicose, putrescine, L-pyroglutamic acid, D-raffinose, L-rhamnose, D-ribose, salicin, sedoheptulosan, L-serine, D-sorbitol, stachyose, succinamic acid, succinic acid, sucrose, D-tagatose, thymidine, thymidine 5′-monophosphate, D-trehalose, turanose, Tweens 40 and 80, uridine, uridine 5′-monophosphate, xylitol, and D-xylose.

Positive for alkaline phosphatase, β-galactosidase, and pyrrolidonyl arylamidase, but negative for *N*-acetyl-β-glucosaminidase, gelatin hydrolysis, β-glucosidase, β-glucuronidase, urease, and fermentation of glycogen, D-lactose, D-mannitol, and D-ribose (API Coryne tests). Positive for esterase (C4), esterase lipase (C8), leucine arylamidase, naphthol-AS-BI-phosphohydrolase, and trypsin, and weakly positive for cystine arylamidase and valine arylamidase (API ZYM tests). Additional phenotypic characteristics are shown in Table 114. The major fatty acids are $C_{17:0}$ anteiso, $C_{15:0}$ anteiso, and $C_{15:0}$ iso. The predominant menaquinone is MK8(H_2). The polar lipid pattern contains phosphatidylglycerol as a major component but lacks diphosphatidylglycerol and phosphatidylinositol.

Source: sand sediment of Samyang Beach, Jeju Island, Republic of Korea.

DNA G+C content (mol%): 70.7 (T_m).

Type strain: SST-8, JCM 14546, KCCM 42316, NRRL B-41420.

Sequence accession no. (16S rRNA gene): DQ344485.

23. **Brevibacterium sandarakinum** Kämpfer, Schäfer, Lodders and Busse 2010, 911[VP]

san.da.ra.ki′num. N.L. neut. adj. *sandarakinum* (from Gr. neut. adj. *sandarakinos -e -on*) of light-red color.

Aerobic, Gram-stain-positive, nonmotile actinomycete which does not form a clear rod–coccus cycle on nutrient agar. After 12 h growth, cells are coccoid (0.8–1.2 µm) and occur singly; after 24 h cells are coccoid to oval. Good growth occurs after 3 d of incubation on nutrient agar at 25–30°C. Growth occurs between 4°C (weak) and 36°C (but not above this temperature), from pH 5.5–12.5 (optimally from pH 7.5–9.5), and in the presence of 1–10% NaCl.

Acetate (weak), *cis*-aconitate, citrate, fumarate (weak), D-galactose, D-glucose, glutarate, histidine, DL-3-hydroxybutyrate, D-mannose, 2-oxoglutarate, propionate, pyruvate, ribose, and D-sorbitol are used as sole carbon sources, but *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, *trans*-aconitate, D-adonitol, 4-aminobutyrate, L-arabinose, arbutin, azelate, cellobiose, D-fructose, *myo*-inositol, itaconate, D-maltitol, maltose, D-mannitol, melibiose, mesaconate, 2-oxoglutarate, putrescine, L-rhamnose, salicin, sucrose, trehalose, and D-xylose are not. Additional phenotypic characteristics are shown in Table 114.

Major fatty acids are anteiso-branched fatty acids. Menaquinones include MK-8(H_2), MK-7(H_2), and minor amounts of MK-9(H_2). The polar lipid profile includes diphosphatidylglycerol, phosphatidylglycerol, an unidentified aminophospholipid, an unidentified glycolipid, an unidentified polar lipid, and minor amounts of three unidentified phospholipids. Cadaverine and putrescine are major components in the polyamine profile.

Source: a sample from the wall of a house colonized with molds in Jena, Germany.

DNA G+C content: not determined.

Type strain: 01-Je-003, CCM 7649, DSM 22082.

Sequence accession no. (16S rRNA gene): FN293377.

Additional comments: the type strain of *Brevibacterium sandarakinum* showed relatively low DNA–DNA relatedness to *Brevibacterium marinum* (31.0%, reciprocal 35.7%) and *Brevibacterium picturae* (36.3%, reciprocal 37.9%) (Kämpfer et al., 2010).

24. **Brevibacterium sanguinis** Wauters, Haase, Avesani, Charlier, Janssens, Van Broeck and Delmée 2004a, 1425[VP] (Effective

publication: Wauters, Haase, Avesani, Charlier, Janssens, Van Broeck and Delmée 2004b, 2831.)

san′gui.nis. L. gen. n. *sanguinis* of blood, because most strains were isolated from blood.

Aerobic, Gram-stain-positive, nonmotile actinomycete which shows a coryneform morphology. Colonies are grayish white, opaque, somewhat sticky, and reach a diameter of 2 mm after 48 h at 37°C on blood agar.

Gelatin, tyrosine, and xanthine are degraded. D-Arabinose, L-fucose, gluconate, glucose, glycerol, maltose, *myo*-inositol, *N*-acetylglucosamine, sucrose, trehalose, and turanose are used as carbon sources (API 50CH tests and ID 32 GN strips). Does not produce acid from glucose or other carbohydrates. Positive for alkaline phosphatase, esterase (C4), esterase lipase (C8), leucine arylamidase, acid phosphatase, and phosphoamidase (API ZYM tests). Does not hydrolyze esculin; methanethiol is produced from L-methionine. Quinate and γ-aminobutyrate are assimilated and alkalinized on Simmons' mineral base. Tyramine is assimilated and acidified on Simmons' mineral base by most strains.

Highly sensitive to thallium acetate. The major fatty acids are $C_{15:0}$ anteiso and $C_{17:0}$ anteiso.

DNA G+C content (mol%): 69.9 (T_m).

Type strain: CF63, CCUG 47857, DSM 15677, JCM 13386.

Sequence accession no. (16S rRNA gene): AJ564859.

ERKO STACKEBRANDT AND PETER SCHUMANN

Cel.lu.lo.mo.na.da.ce′a.e. N.L. fem. n. *Cellulomonas* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Cellulomonadaceae* the *Cellulomonas* family.

Members exhibit a **large variety of morphological forms which often change during growth and under the influence of defined external factors** such as the kind of culture (liquid, chemostat, agar), degree of aeration, and the kind of C- and N-sources. Slender irregular rods of varying length, which may show primary branching, short filaments, and coccoid forms, may occur in late exponential phase cultures; vegetative mycelia with the oldest parts of the mycelium fragmenting into sections of different size and more or less irregular shape may occur. Fragmentation may continue to yield rod-like cells of coryneform appearance and arrangement; aerial mycelium is not formed. **Motile by means of one or several polar or subpolar flagella or by means of peritrichous flagella; some species are nonmotile**. Gram-stain-positive, but many of the older cells stain Gram-negative. **Aerobic to facultatively anaerobic**, producing acid from a variety of carbohydrates. Strains for which information is available form lactic acid and/or acetic acid as the main acidic intermediary products of glucose dissimilation. Glucose is degraded via the Embden–Meyerhof–Parnas pathway and the hexose-monophosphate shunt.

Mycolic acids and diagnostic whole-cell sugars are absent. Cross-linkage of the peptidoglycan is by the A type; **diagnostic amino acids are either ornithine or lysine**. **Interpeptide bridges contain either aspartic acid or glutamic acid**; **L-Thr in combination with a dicarboxylic amino acid occurs in one genus. 12-Methyltetradecanoic ($C_{15:0}$ anteiso) is the prominent fatty acid; $C_{16:0}$, $C_{15:0}$ iso, $C_{14:0}$, and $C_{17:0}$ anteiso may also occur. Menaquinone MK-9(H_4) is the predominant isoprenoid quinone.** Teichoic acids are absent.

The pattern of 16S rRNA gene signatures consists of nucleotides at positions 120 (A), 131:231 (C–G), 196 (U), 342:347 (C–G), 444:490 (A–U), 580:761 (U–A), 602:636 (c–g), 670:736 (A–U), 822:878 (G–C), 823:877 (G–C), 826:874 (C–G), 827 (U), 843 (U), 950:1231 (U–A), 1047:1210 (G–C), 1109 (C), 1145 (A), 1309:1328 (G–C), 1361 (G), and 1383 (y) (Zhi et al., 2009). Usually found in soil, compost, and cellulose enriched environments such as decaying plant materials, bark, wood, sugar fields, rumen, and activated sludge; occasionally isolated from various clinical specimens.

DNA G+C content (mol%): 68–76.

Type genus: **Cellulomonas** Bergey, Harrison, Breed, Hammer and Huntoon 1923, 154 emend. mut. char. Clark 1953, 50.

Further descriptive information

Phylogenetically a member of the order *Micrococcales*. The family contains the type genus *Cellulomonas* Bergey et al. 1923 emend. Clark 1953 emend. Stackebrandt et al. 1982 and the genus *Oerskovia* Prauser et al. 1970 emend. Lechevalier 1972.

The original description of the family *Cellulomonadaceae* Stackebrandt and Prauser 1991b encompassed the genera *Cellulomonas*, *Oerskovia*, *Promicromonospora*, and *Jonesia*. The rational for including these morphologically and chemotaxonomically heterogeneous genera into the same genus was their placement within the same individual line of descent defined by 16S rRNA gene sequence analysis. In the following years, the number of newly described genera of the order *Actinomycetales* was significantly increased, leading to a refinement of the phylogenetic structure of the family (Rainey et al., 1995). The proposal for a new hierarchic structure of the *Actinobacteria* classis nov. Stackebrandt et al. 1997 led to the exclusion of the genera *Promicromonospora* and *Jonesia*, for which the families *Promicromonosporaceae* Rainey, Ward-Rainey and Stackebrandt and *Jonesiaceae* Stackebrandt, Rainey and Ward-Rainey, respectively, were described. As, at the time of this proposal, the type species of the genus *Rarobacter* Yamamoto et al. 1988 was phylogenetically placed adjacent to *Cellulomonas* and *Oerskovia*, this genus was included in the family *Cellulomonadaceae*. A few years later, with more descriptions released, *Rarobacter* changed its position to an individual branch outside the confines of the family *Cellulomonadaceae*. The genus was therefore excluded from this family and transferred to a new family *Rarobacteraceae* Stackebrandt and Schumann 2000b leaving the family *Cellulomonadaceae* to contain only *Cellulomonas* and *Oerskovia*. For the signatures listed in the family description, 16S rRNA gene sequence information of recent descriptions of *Cellulomonas* (An et al., 2005; Brown et al., 2005a; Jones et al., 2005; Kang et al., 2007; Rivas et al., 2004) and *Oerskovia* species (Stackebrandt et al., 2002a) was taken into account. *Cellulomonas fermentans* has been reclassified as *Actinotalea fermentans* gen. nov. (Yi et al., 2007) which is now placed outside the realm of *Cellulomonadaceae* due to the occurrence of MK-10(H_4) and differences in five signature nucleotides. As the set of 16S rRNA signature nucleotides may change with each newly described species added to the family, we refrain from emending the family description on the basis of these signatures alone.

Genus I. **Cellulomonas** Bergey, Harrison, Breed, Hammer and Huntoon 1923, 154 emend. mut. char. Clark 1952, 50[AL]

Erko Stackebrandt and Peter Schumann

Cel.lu.lo.mo′nas. N.L. n. *cellulosum* cellulose; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Cellulomonas* cellulose monad.

In young cultures, slender, irregular rods ~0.3–0.7 µm × ~1.0–4.0 µm or more which may be straight, angular, or slightly curved; some of the rods are arranged at an angle to each other giving V formations. Occasional cells may show primary branching. A mycelium is produced by one species. Cultures a week or more old usually contain mainly short rods, but a small proportion of the cells may be coccoid. Nonsporeforming. Gram-stain-positive, but the cells are very readily decolorized. Not acid fast. Motile by one (usually polar or subpolar) or a few lateral flagella, or nonmotile. **The cell-wall peptidoglycan contains ornithine; dicarboxylic acids are either glutamic acid or aspartic acid. The major isoprenoid quinones are tetrahydrogenated quinones with nine isoprene units [MK-9(H_4)].** Aerobic; most strains also capable of anaerobic growth as stab cultures. Optimum temperature ~30°C. Growth moderate on peptone-yeast extract media at neutral pH giving opaque, usually convex, white, yellowish, or yellow colonies. **Chemoorganotrophic: metabolism primarily respiratory, but also fermentative; most strains produce acid from glucose both aerobically and anaerobically**. Most strains are cellulolytic and reduce nitrate. Phylogenetically a member of the order *Micrococcales*.

DNA G+C content (mol%): 68.5–76.

Type species: **Cellulomonas flavigena** (Kellerman and McBeth 1912) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 165 (*Bacillus flavigena* Kellerman and McBeth 1912, 488).

Further descriptive information

Young cultures consist of slender, irregular rods ranging between ~0.4–0.8 µm in diameter. The rods vary considerably in length and may appear as short filaments in late exponential phase cultures (24 h) when examined by the methods described by Cure and Keddie (1973). They may also show primary branching. As growth proceeds, the rods become shorter and V formations become more obvious. Cultures a week or more old are usually composed mainly of short rods, but a proportion of the cells may be coccoid. When placed on fresh solid medium, growth of coccoid cells occurs by elongation from one or sometimes two parts of the cell to give rods which appear club-shaped or jointed. However, they do not show the marked rod–coccus cycle characteristic of *Arthrobacter* and *Brevibacterium*. Only *Cellulomonas humilata* forms a mycelium with true branching that fragments into diphtheroid and coccoid elements (Collins and Pascual, 2000).

Moderate growth occurs in air at 30°C on meat extract, peptone agar, or yeast-extract, peptone-based agar media at near neutral pH (Keddie and Jones, 1981). Colonies on such media are opaque, usually convex, ~1–3 min in diameter, and usually yellow, but sometimes white. *Cellulomonas humilata* forms branched, filamentous microcolonies (Gledhill and Casida, 1969). Some strains grow at 10°C, some at 5°C, and the maximum temperatures are in the range 36–43°C (cited in Stackebrandt and Keddie, 1986). If tested, strains do not survive heating at 63°C for 30 min (Keddie et al., 1966). All strains grow best aerobically and most give markedly reduced growth under anaerobic conditions; a few are aerobic or give equivocal results (Keddie, 1974; Keddie and Cure, 1977). *Cellulomonas humilata* is microaerophilic (Gledhill and Casida, 1969). The main products of glucose dissimilation in resting cell suspensions of several type strains are acetic acid, L-lactic acid, formic acid, succinic acid, ethanol, and CO_2. The major acid produced from glucose in growing cultures is acetic acid; most strains additionally produce L-lactic acid (Stackebrandt and Kandler, 1979, 1980b). Lactic acid is the main end product of sugar dissimilation by *Cellulomonas humilata* (Gledhill and Casida, 1969); end products were not determined for strains described in the past years. The major route for glucose dissimilation is the Embden–Meyerhof–Parnas pathway; a small amount of glucose is metabolized via the hexose monophosphate pathway (Stackebrandt and Kandler, 1974, 1980b).

Biotin and thiamine are the only exogenous organic growth factors required by the type strains of *Cellulomonas flavigena*, *Cellulomonas biazotea*, *Cellulomonas cellasea*, *Cellulomonas gelida*, and *Cellulomonas uda* (Keddie et al., 1966); when provided with these vitamins, growth occurs in suitable mineral media with glucose as carbon and energy source and an ammonium salt (or nitrate for most strains) as nitrogen source (Owens and Keddie, 1969).

Little information is available on the habitats of *Cellulomonas* species; most of the original cultures were isolated from soil (Bergey et al., 1923), and this has generally been considered to be their major habitat. Decayed wood, cellulose-containing material, compost, and municipal waste were other sources of cellulomonads. Strains of *Cellulomonas denverensis* and *Cellulomonas hominis*, rare human pathogens, were isolated from blood, cerebrospinal fluid, and some other specimen (Brown et al., 2005a; Funke et al., 1995).

A wide range of carbohydrate-binding modules, carbohydrate esterases, and glycoside hydrolases have been studied in detail at the molecular level. Several enzymes have been identified to be involved in the hydrolysis of xylane (xylanases), cellulose (endo-1,4-glucanases, β-glucosidase, cellobiohydrolases), chitin (chitinase), and mannan (β-mannanase). Most of these studies were carried out on *Cellulomonas flavigena* and *Cellulomonas fimi*. The molecular data on these enzymes were compiled by Stackebrandt et al. (2002b). The literature contains more examples of novel cellulomonad enzymes, but evaluation of their properties is confined to function and application. As long as comparative studies of these enzymes on a wider selection of *Cellulomonas* strains is missing, the significance of this data for classification is restricted.

Pathogenicity. A polyphasic study of two bacterial strains isolated from cerebrospinal fluids of a male and a female patient, respectively, revealed that the isolates belong to the genus *Cellulomonas* and represent a new species, *Cellulomonas hominis* (Funke et al., 1995). Although no patients' records were available for the evaluation of the clinical significance of the

isolates, this was the first report on members of the genus *Cellulomonas* that were isolated from clinical specimens. Because of lacking evidence for its pathogenicity, *Cellulomonas hominis* has been affiliated to risk group 1 (Merkblatt B 006 der Berufsgenossenschaft der Chemischen Industrie, July 2005, Germany). Three additional clinical isolates from cerebrospinal fluid (strain W7335), pilonidal cyst (strain W7336), and a lip wound (strain W7387) have been identified as *Cellulomonas hominis* mainly on the basis of DNA–DNA hybridization (Brown et al., 2005a). Two isolates from a patient with endocarditis from Denver (W6929^T from blood and W6124 from a homograft valve) and a blood isolate (strain W6117) from a patient from Ohio differed in their ability to ferment sorbitol and had DNA–DNA similarity values sufficiently different from *Cellulomonas hominis* to be classified in a new species, *Cellulomonas denverensis* (Brown et al., 2005a). *Cellulomonas hominis* strains DMMZ CE40^T and DMMZ CE39 were susceptible to tetracycline, rifampin, and vancomycin (Funke et al., 1995). Rifampin and vancomycin were also suitable antimicrobial agents for *Cellulomonas denverensis* (Brown et al., 2005a). Additionally, clarithromycin, clindamycin, imipenem, and minocycline were considered active against *Cellulomonas hominis* and *Cellulomonas denverensis* strains (Brown et al., 2005a). Two isolates from blood cultures from patients at the Gaziantep University Hospital (southeast Turkey) were identified as members of the genus *Cellulomonas* that were susceptible to teicoplanin, rifampin, vancomycin, gentamicin, and ampicillin-sulbactam and were reported by Balci et al. (2002). Although it is difficult to differentiate between true infection and contamination and to identify *Cellulomonas* strains unambiguously by phenotype-based commercial diagnostic test systems, the role of members of the genus *Cellulomonas* as potential pathogens in clinical cases, especially in immunocompromised patients, must be taken into consideration.

The environmental type strain of *Cellulomonas bogoriensis* (Jones et al., 2005) is susceptible to a wide range of antibiotics; resistance and susceptibility data are also available for *Cellulomonas terrae* (An et al., 2005).

Enrichment and isolation procedures

Cultures may be enriched in a mineral-based medium containing a low (0.05–0.1%) concentration of yeast extract to provide the necessary organic growth factors with filter paper as cellulose source. This is followed by plating on a similar solid medium but containing cellulose in dispersed form. Cellulolytic bacteria produce colonies surrounded by zones of clearing. Direct plating on cellulose agar, or R2A medium without previous enrichment, may also be used. The methods are not selective for *Cellulomonas* and isolates must be screened for those with a coryneform morphology.

Suspensions or macerates of the material being examined (soil, compost, etc.) may be streaked directly onto the surface of cellulose agar (Stewart and Leatherwood, 1976) of the following composition (g/100 ml of distilled water): $NaNO_3$, 0.1; K_2HPO_4, 0.1; KCl, 0.05; $MgSO_4$, 0.05; yeast extract, Difco, 0.05; agar, 1.7; ball-milled filter paper, 0.1; glucose 0.1; pH 7.0. To prepare the ball-milled filter paper, a 3% (w/v) aqueous suspension of filter paper (Whatman no. 1) is ball-milled for 3 d. Other suitable sources of dispersed cellulose may be used, e.g. microcrystalline cellulose (Avicel, FNIL) at a concentration of 0.1% (w/v) (Kaufmann et al., 1976). In other similar versions of the medium, the glucose is omitted. The plates are incubated at 30°C for 5–7 d; colonies showing zones of clearing are replated on the same medium until pure cultures are obtained. Yellow to yellowish isolates which show a coryneform morphology in combination with cellulolytic activity are presumptive members of the genus *Cellulomonas*.

Cellulomonas enrichments may be prepared by a method similar to that described by Han and Srinivasan (1968). A liquid version of the cellulose agar described above is used but with the glucose omitted and with strips of filter paper replacing the finely divided cellulose. Other mineral bases may be used, e.g. that of Han and Srinivasan (1968), Owens and Keddie (1969), Bagnara et al., (1985), and Malekzadeh et al. (1993). Xylanic strains may be isolated on XED medium (xylan, 0.7%; yeast extract, 0.3%; agar, 2.5%) (Rivas et al., 2004). Strains from clinical specimens were cultured on Columbia agar or Trypticase soy agar (Becton Dickinson) with 5% sheep blood at 37°C in a 5% CO_2 atmosphere. Alkaliphilic cellulomonas may be enriched at 37°C on an alkaline casein medium containing the following (g/l): glucose (10), Difco peptone (5), Difco yeast extract (5), K_2HPO_4 (1), $MgSO_4 \cdot 7H_2O$ (0.2), NaCl (40), Na_2CO_3 (10), casein (20), and agar (20) (Jones et al., 2005). Cultivation is achieved in glucose alkaline medium consisting of two parts. Solution A contained the following dissolved in 800 ml distilled water and sterilized: glucose (10 g), Difco peptone (5 g), Difco yeast extract (5 g), K_2HPO_4 (1 g), and $MgSO_4 \cdot 7H_2O$ (0.2 g). Solution B contained 40 g NaCl and 10 g Na_2CO_3 dissolved in 200 ml distilled water and sterilized. The two solutions were then mixed. Solid medium was prepared by adding agar (2%, w/v) to solution A before sterilization (Duckworth et al., 1996).

Maintenance procedures

For short-term preservation (a few weeks), stab cultures (by loop) in TSX semisolid medium (Keddie et al., 1966) should remain viable for 3 months or more at room temperature (20°C). For long-term preservation (several years), cultures may be preserved by lyophilization.

Taxonomic comments

Most species of *Cellulomonas* which have been included in taxonomic studies have been represented only by single strains. It is therefore difficult to know whether or not the few phenetic differences reported to occur between species (see Table 115) are species-specific or only strain-specific. As all species described around 1913 resembled each other phenetically, only *Cellulomonas flavigena* was recognized in the 8th edition of the *Manual*, while *Cellulomonas biazotea*, *Cellulomonas cellasea*, *Cellulomonas gelida*, and *Cellulomonas uda* were considered to be subjective synonyms and *Cellulomonas fimi* a possible subjective synonym of *Cellulomonas flavigena* (Keddie, 1974). However, the reduction to a single species was questioned by Braden and Thayer (1976) on the basis of serological relatedness using purified cell wall preparations as antigens. DNA–DNA reassociation studies on representatives of *Cellulomonas* revealed the presence of seven genetically well-defined species (Stackebrandt and Kandler, 1979); "*Cellulomonas subalbus*" NCIB 8075

was found to be identical with *Cellulomonas gelida* ATCC 488[T] on the basis of genetic and phenotypic evidence. The Approved Lists of Bacterial Names (Skerman et al., 1980) contains six species: *Cellulomonas flavigena*, *Cellulomonas biazotea*, *Cellulomonas gelida*, *Cellulomonas uda*, *Cellulomonas fimi*, and *Cellulomonas cellasea.* A seventh species, *Cellulomonas cartae*, was described later, and *Nocardia cellulans*, *Oerskovia xanthineolytica*, *Brevibacterium fermentans*, and *Brevibacterium lyticum* were considered to be subjective synonyms of *Cellulomonas cartae* (Stackebrandt and Kandler, 1980a). As the specific epithet *cellulans* (Metcalfe and Brown, 1957) antedates the name *cartae* (Stackebrandt and Kandler, 1980a), the latter epithet was illegitimate and the legitimate name for this species is *Cellulomonas cellulans* (Stackebrandt and Keddie, 1986). Differences in biochemical and morphological characters (Keddie and Jones, 1981) and phylogenetic analyses (Stackebrandt et al., 1980; Stackebrandt et al., 1982) including newly described and undescribed species indicate that *Cellulomonas cellulans* groups more distantly from the core of *Cellulomonas* than observed previously (Rainey et al., 1995). *Cellulomonas cellulans* clusters next to members of the family *Promicromonosporaceae* and differs in chemotaxonomic characteristics from established genera resulting in the reclassification of this species as *Cellulosimicrobium cellulans* (Schumann et al., 2001).

The species *Cellulomonas turbata* was created by the union of *Cellulomonas* and *Oerskovia* (Stackebrandt et al., 1982). However, even at the time of unification, it was evident that *Cellulomonas turbata* differed from all other *Cellulomonas* species in its susceptibility against *Oerskovia* phages (Prauser, 1986), in the amino acid composition of peptidoglycan, and in differences in the formation of mycelia. The emended genus *Oerskovia* with *Oerskovia turbata* as the type species was reestablished by Stackebrandt et al. (2002a). Depending upon the number and phylogenetic origin of reference sequences, *Oerkovia* species may branch as a clade of their own within the radiation of *Cellulomonas* (e.g. Kang et al., 2007). This indicates that distinctness in morphological and chemotaxonomic traits does not always correlate with phylogenetic separation. A similar case is *Actinotalea* (*Cellulomonas*) *fermentans* that tends to occupy different positions within *Cellulomonas* (e.g. An et al., 2005).

Phylogeny. *Cellulomonas* strains share >95% 16S rRNA gene sequence similarities with strains of *Oerskovia.* Independent of the number and selection of outgroup sequences from the order *Micrococcales*, *Oerskovia* strains branch within the radiation of *Cellulomonas* type strains. It is worth noting that the two *Cellulomonas* type strains from clinical specimens, representing *Cellulomonas hominis* and *Cellulomonas denverensis*, cluster specifically with oerskovias, some of which are of clinical relevance as well. The chemotaxonomic clustering of *Cellulomonas* strains according to the dicarboxylic amino acid of the peptidoglycan interpeptide bridge (glutamic versus aspartic acid) is not reflected by the phylogenetic position of the strains. Asp-containing strains are found in three lineages; specific relationships are found between *Cellulomonas flavigena* and *Cellulomonas persica* and between *Cellulomonas fermentans* and *Cellulomonas bogoriensis.* The mostly low bootstrap values separating the Asp-containing strains, make possible a different branching when more strains will be included into the genus. Similarly, the position of the *Oerskovia* lineage is of low statistical significance, and this position should not be considered settled. A few signature base pairs define members of the two highly related genera: At positions 185:192, 602:636, 612:628, and 1120:1153 cellulomonads exhibit the composition R–Y, C–G, Y–G, and C–G, while oerskovias have the composition C–G, G–U, U–A, and U–A, respectively. Recently the species *Cellulomonas fermentans* has been reclassified as *Actinotalea fermentans* (Yi et al., 2007). The decision was based on the change of phylogenetic position of *Cellulomonas fermentan* due to the addition of the 16S rRNA gene sequence of a new member of *Micrococcales*, described as *Demequina aestuarii* (Yi et al., 2007).

Some of the close 16S rRNA gene sequence relationships are supported by moderate DNA–DNA similarity values among the type strains, e.g. *Cellulomonas biazotea* and *Cellulomonas fimi* (50% homology) and *Cellulomonas gelida* and *Cellulomonas uda* (45% similarity; Stackebrandt and Kandler, 1979; 66%, Elberson et al., 2000). A similar range has also been determined for *Cellulomonas flavigena* and *Cellulomonas uda* (range 41–56%; Elberson et al., 2000) and for *Cellulomonas flavigenea*, *Cellulomonas iranensis*, and *Cellulomonas persica* (39–62%), and *Cellulomonas persica* and *Cellulomonas gelida* (48%; Elberson et al., 2000). *Cellulomonas gelida* is genotypically and phenotypically indistinguishable from the strain named "*Cellulomonas subalbus*" (NCIB 8075) (Stackebrandt and Kandler, 1979), thus supporting the earlier proposal by Clark (1953) to reduce "*Cellulomonas* subalbus" to synonymy.

Low values have been determined for *Cellulomonas cellasea* (<35%) and other *Cellulomonas* strains, between *Cellulomonas denverensis* and *Cellulomonas hominis* (24–33%; Brown et al., 2005a) and between *Cellulomonas xylanilytica* XIL11[T] and *Cellulomonas humilata* ATCC 25174[T] (37%; An et al., 2005) (Figure 150).

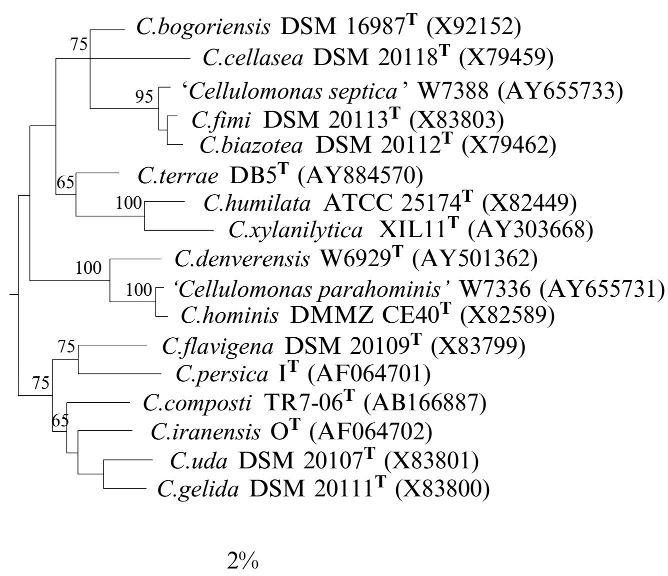

FIGURE 150. 16S rRNA gene sequence dendrogram (De Soete, 1983) of members of the genus *Cellulomonas*, represented by their type strains and two non-validly described species. Bootstrap values (>60%) of 1000 resamplings (Felsenstein, 1989) are indicated at nodes. Members of the genus *Cellulosimicrobium* define the root. The scale represents 2% inferred nucleotide changes.

List of species of the genus *Cellulomonas*

1. **Cellulomonas flavigena** (Kellerman and McBeth 1912) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 165[AL] (*Bacillus flavigena* Kellerman and McBeth 1912, 488)

fla.vi.ge′na. L. adj. *flavus* yellow; L. suff. *genus -a -um* (from L. v. *gigno* to produce, give birth to, beget) producing; N.L. fem. adj. *flavigena* yellow-producing.

Cell morphology as given for the genus. Colonies irregular, 0.9–3.1 mm in diameter, lemon yellow, and opaque, flat, edge fimbriate. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, cells grow on L-arabinose, D-galactose, cellobiose, and trehalose. The major fatty acid is $C_{15:0}$ anteiso with smaller amounts of $C_{15:0}$ and traces of other iso-, anteiso- and straight chain saturated acids.

DNA G+C content (mol%): 72.7–74.8 (T_m)

Type strain: ATCC 482, CCUG 12162, CCUG 28996, CFBP 4223, CIP 82.10, DSM 20109, NBRC 3754, JCM 1489, LMG 16263, NCAIM B.01383, VKM Ac-1137.

Sequence accession no. (16S rRNA gene): X83799.

2. **Cellulomonas biazotea** (Kellerman, McBeth, Scales and Smith 1913) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 158[AL] (*Bacillus biazoteus* Kellerman, McBeth, Scales and Smith 1913, 506)

bi.a.zo′te.a. L. prefix *bis*, *bi* two; N.L. n. *azotum* (from Fr. n. *azote*) nitrogen; L. fem. suff. *-ea* suffix used with various meanings, but signifying in general made of or belonging to; N.L. fem. adj. *biazotea* two nitrogen sources utilized (i.e. organic and inorganic).

Cell morphology as given for the genus. Colonies circular, slightly irregular, 0.6–2.8 mm in diameter, canary yellow, and opaque, low convex, edge entire or erose. Physiological, biochemical, and chemotaxonomic characters are given in Table 115 and in the generic description. In addition, cells grow on L-arabinose, D-galactose, cellobiose, and trehalose. The major cell-wall sugar is rhamnose while galactose, mannose, and 6-desoxytalose are minor components. The major fatty acid is $C_{15:0}$ anteiso with smaller amounts of $C_{15:0}$ iso.

DNA G+C content (mol%): 71.5–75.6 (T_m).

Type strain: ATCC 486, CFBP 4269, CIP 82.11, DSM 20112, NBRC 12680, JCM 1340, LMG 16695, NCAIM B.01385, VKM Ac-1410.

Sequence accession no. (16S rRNA gene): X79462, X83802.

3. **Cellulomonas bogoriensis** Jones, Grant, Duckworth, Schumann, Weiss and Stackebrandt 2005, 1713[VP]

bo.go.ri.en′sis. N.L. fem. adj. *bogoriensis* pertaining to Lake Bogoria, Kenya.

Cell morphology as given for the genus. On alkaline GAM agar, colonies are opaque, glistening, pale yellow, circular, and convex or domed, the margins are entire, and they are about 2 mm in diameter after 2–3 d at 37°C. Colonies are viscous or slimy and tend to clump when scraped with a loop. On neutral tryptone soy agar (Oxoid), growth is less vigorous, colonies are translucent and yellow and generally <1 mm in diameter. The temperature range for growth is 20–37°C, with an optimum around 30–37°C. No growth occurs at 15 or 45°C. Alkaliphilic and slightly halotolerant. Growth occurs at pH values of 6.0–10.5, with an optimum around pH 9–10. No growth occurs at pH 11 or pH 5.5. Growth below pH 7 is less vigorous and less abundant. Growth occurs in medium containing 0–8.0% (w/v) NaCl. Chemoorganotrophic. Growth occurs on complex substrates such as yeast extract and peptone. Facultatively anaerobic. Physiological, biochemical, and chemotaxonomic characters are given in Table 115 and in the generic description. In addition, acid is produced aerobically and anaerobically (API 50 CH) from the following: L-arabinose, D-xylose, D-glucose, D-fructose, D-mannose, cellobiose, maltose, sucrose, trehalose, gentiobiose, D-turanose, D-lyxose, rhamnose (weak), and 5-ketogluconate (weak). Utilizes amygdalin, arbutin, and salicin. Unable to utilize ribose, lactose, galactose, melibiose, D-raffinose, glycogen, glycerol, erythritol, inositol, mannitol, sorbitol, xylitol, arabitol, gluconate, or lactate. Hydrolyzes carboxymethylcellulose and amorphous cellulose. The following enzymes are produced (API ZYM, API Coryne): C4-esterase, C8-esterase, leucine arylamidase, α-chymotrypsin, α-glucosidase, β-glucosidase, and pyrazinamidase. Major fatty acids are $C_{15:0}$ anteiso and $C_{16:0}$; $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{14:0}$, $C_{15:1}$anteiso, $C_{14:0}$ iso, and $C_{17:0}$ anteiso occur in amounts <6%. Phosphatidylglycerol is the only identified phospholipid; three unknown phospholipids occur as well.

Source: the littoral zone of Lake Bogoria, Kenya, at Acacia Camp.

DNA G+C content (mol%): 71.5.

Type strain: 69B4, CIP 108683, DSM 16987.

Sequence accession no. (16S rRNA gene): AJ863164, X92152.

4. **Cellulomonas cellasea** (Kellerman, McBeth, Scales and Smith 1913) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 158[AL] (*Bacillus cellaseus* Kellerman, McBeth, Scales and Smith 1913, 508)

cel.la′se.a. N.L. n. cellulosum cellulose; L. fem. suff. *-ea* suffix used with various meanings, but signifying in general made of or belonging to; N.L. fem. adj. *cellasea* pertaining to cellulose.

Cell morphology as given for the genus. Colonies circular, becoming irregular, 0.6–3.4 mm diameter, lemon yellow, opaque, edge entire or slightly erose. Physiological, biochemical, and chemotaxonomic characters are given in Table 115 and in the generic description. In addition, cells grow on L-arabinose, D-galactose, cellobiose, and trehalose. The major cell-wall sugar is rhamnose; mannose and 6-desoxytalose occur in smaller amounts.

DNA G+C content (mol%): 75.0 (T_m).

Type strain: ATCC 487, CFBP 4260, CIP 102222, DSM 20118, NBRC 3753, JCM 9967, LMG 16323, NCCB 29015, VKM Ac-1136.

Sequence accession no. (16S rRNA gene): X79459, X83804.

5. **Cellulomonas composti** Kang, Im, Jung, Kim, Goodfellow, Kim, Yang, An and Lee 2007, 1259

com.pos′ti. N.L. n. *compostum* compost; N.L. gen. n. *composti* of compost.

Cell morphology as given for the genus. Nonmotile. Colonies on R2A agar plates are circular, smooth, yellow

circles within 3 d at 25°C. Optimal growth occurs at 30°C and pH 6.8–7.5. Aerobic or facultatively anaerobic. Utilizes D-glucose, maltose, and glycogen as sole carbon sources. Catalase negative. Acid is produced aerobically and anaerobically from L-arabinose, D-xylose, D-galactose, D-glucose, D-fructose, D-mannose, D-cellobiose, D-maltose, sucrose, D-trehalose, starch, glycogen, and gentiobiose. Acid is produced weakly under anaerobic conditions from D-ribose, D-lactose, inulin, and D-lyxose. Hydrolyzes gelatin weakly. Positive for nitrate reduction. β-Glucosidase, amylase, cellulose, and DNase are produced. Negative for catalase and urease. Physiological, biochemical, and chemotaxonomic characters are given in Table 115 and in the generic description. Cell-wall sugars are mannose and glucose.

Source: compost from a cattle farm near Daejeon, Republic of Korea.

DNA G+C content (mol%): 73.7 (HPLC).

Type strain: TR7-06, JCM 14898, KCTC 19030, NBRC 100758.

Sequence accession no. (16S rRNA gene): AB166887.

6. **Cellulomonas denverensis** Brown, Frazier, Morey, Steigerwalt, Pellegrini, Daneshvar, Hollis and McNeil 2005b, 1395[VP] (Effective publication Brown, Frazier, Morey, Steigerwalt, Pellegrini, Daneshvar, Hollis and McNeil 2005a, 1736.)

den.ver.en′sis, N.L. fem. adj. *denverensis* of or pertaining to Denver, Colorado, USA, the city of origin of the type strain.

Cell morphology as given for the genus. Cells are short (1 μm), thin, Gram-stain-positive, nonsporeforming rods that are motile by polar and lateral flagella. Colonies are circular, smooth, and convex, and are pale yellow after about 3 d. Cells are fermentative. Growth occurs at 35 and 45°C but not at 25°C. Catalase positive. Physiological, biochemical, and chemotaxonomic characters are given in Table 115 and in the generic description. Acid is produced from cellobiose, D-galactose, D-glucose, lactose, maltose, mannose, L-rhamnose, salicin, D-sorbitol, sucrose, D-trehalose, and D-xylose, and sometimes from L-arabinose (2/3), glycerol (2/3), and melibiose (1/3). No acid is produced from adonitol, dulcitol, *i*-erythritol, *i*-*myo*-inositol, D-mannitol, melezitose, or raffinose. The diagnostic whole-cell sugars are mannose, ribose, and rhamnose.

Source: blood and other specimens of human origin.

DNA G+C content (mol%): 68.5.

Type strain: W6929, ATCC BAA-788, CCUG 18431, DSM 15764, JCM 14733.

Sequence accession no. (16S rRNA gene): AY501362.

7. **Cellulomonas fimi** (McBeth and Scales 1913) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 166[AL] (*Bacterium fimi* McBeth and Scales 1913, 30)

fi′mi. L. n. *fimus* dung; L. gen. n. *fimi* of dung.

Cell morphology as given for the genus. Colonies circular, 0.4–1.8 mm in diameter, cream or yellowish, opaque, glistening, edge entire. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. The major cell-wall sugar is rhamnose; fucose and glucose are minor components.

DNA G+C content (mol%): 71.3–72.0 (T_m).

Type strain: ATCC 484, CCUG 24087, CFBP 4254, CIP 102114, DSM 20113, HAMBI 93, NBRC 15513, JCM 1341, LMG 16345, NCAIM B.01386, NCCB 29016, NCTC 7547, VKM Ac-1411.

Sequence accession no. (16S rRNA gene): X79460, X83803.

8. **Cellulomonas gelida** (Kellerman, McBeth, Scales and Smith 1913) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 162[AL] (*Bacillus gelidus* Kellerman, McBeth, Scales and Smith 1913, 510)

ge′li.da. L. fem. adj. *gelida* very cold.

Cell morphology as given for the genus. Colonies circular, 0.8–2 mm in diameter, cream or yellowish, opaque, convex domed, edge entire or slightly erose. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, cells grow on L-arabinose, D-galactose, cellobiose, and trehalose. The major fatty acid is $C_{15:0}$ anteiso with smaller amounts of $C_{15:0}$ and traces of other iso-, anteiso- and straight chain saturated acids. [These studies were carried out on "*C. subalbus*" C222 (NCIB 8075) which has been regarded as a strain of *Cellulomonas gelida*.]

DNA G+C content (mol%): 72.4–74.4 (T_m)

Type strain: ATCC 488, CFBP 4257, CIP 102221, DSM 20111, NBRC 3748, JCM 1490, LMG 16697.

Sequence accession no. (16S rRNA gene): X83800.

9. **Cellulomonas hominis** Funke, Ramos and Collins 1996, 362[VP] (Effective publication: Funke, Ramos and Collins 1995, 2096.)

ho′mi.nis L. gen. n. *hominis* of man, indicating that the two isolates included in the present description are derived from humans and not from the environment.

Cell morphology as given for the genus. The cells are short (1 μm), thin rods without irregular branching. Nonsporeforming. The cells are motile. The colonies are circular, smooth, convex, and whitish initially but with yellowish pigmentation in about 3 d. The colony size is about 1 mm in diameter after 24 h of incubation at 37°C in 5% CO_2. Physiological, biochemical and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, acid is produced from L-arabinose, cellobiose, dextrin, D-fructose, galactose, β-gentiobiose, gluconate, glucose, glycerol, lactose, maltose, mannose, α-methyl-D-mannoside, rhamnose, salicin, sucrose, xylose, and β-methylxyloside. No acid is produced from adonitol, dulcitol, erythritol, inositol, 2-ketogluconate, or mannitol. The following enzyme activities are detected: esterase (C4), esterase lipase (C8), leucine arylamidase, α-glucosidase, and α-mannosidase. Valine arylamidase, chymotrypsin, β-glucuronidase, and α-fucosidase are not present.

DNA G+C content (mol%): 73–76 (HPLC).

Type strain: ATCC 51964, CCUG 34783, CIP 104574, DMMZ CE40, DSM 9581, NBRC 16055, JCM 12133, LMG 17240.

Sequence accession no. (16S rRNA gene): not available.

10. **Cellulomonas humilata** (corrig. Gledhill and Casida 1969) Collins and Pascual 2000, 662[VP] (*Actinomyces humiferus* Gledhill and Casida 1969, 119)

hu.mi.la′ta. L. masc. n. *humus* soil; L. part. adj. *latus -a, -um* borne; N.L. fem. adj. *humilata* soil-borne.

Cells are predominantly filamentous and branched and often have swollen ends. They stain Gram-positive and are non-acid-fast. After prolonged incubation, they usually fragment into diphtheroid or coccoid elements of varied size and shape. In liquid media, growth is granular or flocculent, forming a white sediment without turbidity. Mature colonies are small, opaque, smooth, entire, and convex with a dark central region. Rough colony variants occur occasionally. Pigmentation is not evident. Microaerophilic to aerobic; there is poor or no growth in anaerobic conditions. Growth is not stimulated by increased CO_2 tension. Oxidase negative.

The optimum temperature for growth is approximately 30°C; poor or no growth is observed at 37°C. Does not grow on media lacking organic nitrogen. In addition, little if any growth is obtained in certain chemically defined media or those that contain simple peptones. Cells are sensitive to lysis by lysozyme. Fermentation of sugars produces lactic acid as a major end product and no gas formation. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, casein, esculin, and starch are hydrolyzed, whereas xanthine, tyrosin, and urea are not. Gelatin is weakly decomposed but not liquefied. Litmus milk is acidified and reduced. Nitrates are not reduced to nitrites. Production of indole from tryptophan and of ammonia from peptone and arginine are negative. Methyl-red test is positive, whereas Voges–Proskauer reaction is negative. Hydrogen sulfide is produced. No growth is obtained in the presence of 4% NaCl. Pyruvate, fumarate, 2-oxoglutarate, and gluconate are utilized. Acid is produced from cellobiose, dextrin, D-fructose, D-glucose, D-mannose, D-raffinose, D-xylose, galactose, L-arabinose, maltose, mannitol, melezitose, melibiose, rhamnose, salicin, starch, sucrose, turanose, and β-gentiobiose, whereas acid is not produced from adonitol, dulcitol, inositol, inulin, ribose, or sorbitol. Acid production from glycerol, lactose, and trehalose is variable. Xylane is hydrolyzed. Cell-wall peptidoglycan is of the L-Orn←D-Glu type. Rhamnose is the predominant cell-wall sugar, but glucose and fucose may be present in trace amounts. Thrives in organically rich soil, from which the organism may be recovered in large numbers. The type strain produces acid from glycerol, lactose and trehalose.

Comment: Lysine reported by Collins and Pascual (2000) could not be confirmed as diamino acid of peptidoglycan and the type L-Orn←D-Glu was detected as cited in Stackebrandt et al. (2002a).

Source: organically rich soils.

DNA G+C content (mol%): 73 (Bd).

Type strain: ATCC 25174, CCUG 35596, CIP 104614, JCM 11945, NRRL B-3752.

Sequence accession no. (16S rRNA gene): not available.

11. **Cellulomonas iranensis** Elberson, Malekzadeh, Yazdi, Kameranpour, Noori-Daloii, Matte, Shahamat, Colwell and Sowers 2000, 996[VP]

i.ra.nen′sis. N.L. fem. adj. *iranensis* of or belonging to Iran, where the organism was isolated.

Cell morphology as given for the genus. Irregular, straight, or slightly curved rods 0–4 × 2–54–0 µm, which occasionally exhibit typical coryneform branching. Cells are motile, with 1–4 peritrichous flagella. Gram-stain-positive, but readily decolorized. Colonies are light yellow, approximately 1 mm in diameter, circular, convex, and glossy. Optimal growth temperature is 30°C. Optimal pH for growth is 7.2–7.4. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, produces acid from dextrin. D-ribose and raffinose are not utilized. Starch and gelatin (weakly) are hydrolyzed. Nitrate is reduced to nitrite, DNase produced. Urea hydrolyzed as nitrogen source in cellulose fermentation. Peptidoglycan is of the L-Orn←D-Asp type and contains the sugars rhamnose, glucosamine, and minor amounts of mannose.

Source: forest humus soil located under walnut, fig, hornbeam, mimosa and box trees in Ramsar Forest, 1.6 km south of Ramsar, Iran, along the border of the Caspian Sea.

DNA G+C content (mol%): not available.

Type strain: O, ATCC 700643, DSM 14785, JCM 12410, NBRC 16734, NBRC 101100.

Sequence accession no. (16S rRNA gene): AF064702.

12. **Cellulomonas persica** Elberson, Malekzadeh, Yazdi, Kameranpour, Noori-Daloii, Matte, Shahamat, Colwell and Sowers 2000, 995[VP]

per′si.ca. L. fem. adj. *persica* Persian, from Persia, classical name of Iran, where the organism was isolated.

Cell morphology as given for the genus. Irregular, straight or slightly curved rods 0–6 × 2–04–0 mm, which occasionally exhibit typical coryneform branching. Cells are motile, with 1–4 peritrichous flagella. Gram-stain-positive, but readily decolorized. Colonies are light yellow, approximately 1 mm in diameter, circular, convex, and glossy. Optimal growth temperature is 30°C. Optimal pH for growth is 7.2–7.4. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, acid production from dextrin. Does not utilize D-ribose or raffinose. Starch and gelatin are hydrolyzed, the latter weakly. Nitrate is reduced to nitrite, DNase produced. Urea hydrolyzed as nitrogen source in cellulose fermentation. Peptidoglycan is of the L-Orn←D-Asp type and contains the sugars rhamnose, glucosamine, and minor amounts of mannose.

Source: forest humus soil located under walnut, fig, hornbeam, mimosa, and box trees in Ramsar Forest, 1–6 km south of Ramsar, Iran, along the border of the Caspian Sea.

DNA G+C content (mol%): not available.

Type strain: I, ATCC 700642, DSM 14784, JCM 12411, NBRC 16733, NBRC 101101.

Sequence accession no. (16S rRNA gene): AF064701.

13. **Cellulomonas terrae** An, Im, Yang, Kang, Kim, Jin, Kim and Lee 2005, 1708[VP]

ter′rae. L. gen. n. *terrae* of the earth.

Cell morphology as given for the genus. Grows well under aerobic or facultatively anaerobic conditions at 30°C on R2A agar. Cells are Gram-stain-positive, straight rods,

and produce creamy yellow, circular, smooth colonies. No growth at 4 or 45°C or at 4% NaCl. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, negative for oxidase activity and production of indole and acylamidase, and positive for β-galactosidase, β-glucosidase, and hydrolysis of xylan. Can also use the following as sole carbon sources: arabinose, fructose, galactose, gentiobiose, glycogen, inositol, 5-ketogluconate, mannose, D-melibiose, *N*-acetylglucosamine, rhamnose, starch, and xylane. No growth with the following: acetate, adipate, L-alanine, caprate, citrate, L-fucose, 3-hydroxybenzoate, 3-hydroxybutyrate, 4-hydroxybutyrate, histidine, itaconate, 2-ketogluconate, malate, malonate, propionate, L-proline, phenylacetate, salicin, L-serine, D-sorbitol, suberate, and valerate. Can produce acid from L-arabinose, cellobiose, fructose, galactose, gentiobiose, glycerol, glycogen, glucose, D-lyxose, maltose, mannose, melezitose, melibiose, *N*-acetylglucosamine, raffinose, sucrose, trehalose, D-turanose, and D-xylose. The predominant isoprenoid quinones are MK-9(H_4) and MK-8(H_4). The most abundant cellular fatty acids (>10%) are $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$. The cell-wall sugars are galactose, glucose, and rhamnose.

Source: soil near Yusong in Daejeon City, Republic of Korea.

DNA G+C content (mol%): 73.9 (HPLC).

Type strain: DB5, JCM 14899, KCTC 19081, NBRC 100819.

Sequence accession no. (16S rRNA gene): AY884570.

14. **Cellulomonas uda** (Kellerman, McBeth, Scales and Smith 1913) Bergey, Harrison, Breed, Hammer and Huntoon 1923, 166[AL] (*Bacterium udum* Kellerman, McBeth, Scales and Smith 1913, 514)

u′da. L. fem. adj. *uda* moist, wet.

Cell morphology as given for the genus. Colonies punctiform or circular, 0.2–1.8 mm in diameter, off-white, opaque, smooth and shiny surface, edge entire. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. In addition, cells grow on L-arabinose, D-galactose, cellobiose, and trehalose.

DNA G+C content (mol%): 72 (T_m).

Type strain: ATCC 491, CFBP 4256, CIP 102089, DSM 20107, NBRC 3747, JCM 1492, LMG 16327, NCAIM B.01382, VKM Ac-1140.

Sequence accession no. (16S rRNA gene): X83801.

15. **Cellulomonas xylanilytica** Rivas, Trujillo, Mateos, Martínez-Molina and Velázquez 2004, 535[VP]

xy.la.ni.ly′ti.ca. N.L. n. *xylanum* xylan a vegetal polymer, N.L. adj. *lyticus -a -um* (from Gr. adj. *lutikos -ê -on*) able to loosen, able to dissolve; N.L. fem. adj. *xylanilytica* xylan-dissolving.

Cell morphology as given for the genus. Coccoid or rod-shaped cells (2.4 × 1.4 µm). Colonies on YED medium are smooth, yellow, and usually 1–3 mm in diameter within 7 d at 28°C. Optimal growth temperature is 30°C. Optimal growth pH is 7. Oxidase positive. Physiological, biochemical, and chemotaxonomic characteristics are given in Table 115 and in the generic description. Aerobic or facultatively anaerobic and chemoorganotrophic. In addition, utilizes arabinose, cellulose, gentiobiose, mannose, *N*-acetylglucosamine, starch, and xylan as sole carbon sources. By contrast, no growth occurs in acetate, adipate, caprate, citrate, malate, mannitol, phenylacetate, or ribose. Acid is produced from amygdalin, arbutin, cellobiose, D-fructose, galactose, glucose, glycerol, glycogen, inulin, lactose, D-lyxose, maltose, D-mannose, melezitose, melibiose, D-raffinose, rhamnose, salicin, L-sorbose, sucrose, trehalose, xylitol, D-xylose, methyl α-D-glucoside, methyl α-D-mannoside, *N*-acetylglucosamine, and β-gentiobiose. Amylases, cellulases, β-galactosidase, and xylanases are actively produced. Esculin, casein, and gelatin are hydrolyzed. Nitrate is reduced to nitrite. Arginine dehydrolase, indole, tryptophan deaminase, and urease are not produced. Major fatty acids are $C_{15:0}$ anteiso, $C_{16:0}$, and $C_{18:0}$. Major isoprenoid quinones are MK-9(H_4) and MK-8(H_4). Peptidoglycan is of the L-Orn←D-Glu type (A4β). Cell-wall sugars are rhamnose, mannose, and fucose.

Comment: L-Glu as peptidoglycan interpeptide bridge was erroneously stated in the species description of Rivas et al. (2004).

DNA G+C content (mol%): 73 (T_m).

Type strain: XIL11, CECT 5729, JCM 14281, LMG 21723, NBRC 101102.

Sequence accession no. (16S rRNA gene): AY303668.

Genus II. *Incertae sedis* **Actinotalea** Yi, Schumann and Chun 2007, 155[VP]

Hans-Jürgen Busse

Ac.ti.no.ta′le.a. Gr. n. *aktis -inos* ray; L. fem. n. *talea* a slender staff, rod, stick; N.L. fem. n. *Actinotalea* ray stick.

Gram-stain-positive, coryneform rods exhibiting polymorphism. Nonmotile. **Facultatively anaerobic**. **Diagnostic diamino acid** of the peptidoglycan is L-ornithine and the **interpeptide bridge is D-aspartate**. **Major fatty acids** are **$C_{14:0}$, $C_{15:0}$ anteiso, and $C_{16:0}$**. The **major isoprenoid quinone is MK-10(H_4)**.

DNA G+C content (mol%): 76.

Type species: **Actinotalea fermentans** (Bagnara, Toci, Gaudin and Belaich 1985) Yi, Schumann and Chun 2007, 155[VP] (*Cellulomonas fermentans* Bagnara, Toci, Gaudin and Belaich 1985, 506).

Further descriptive information

Cellulomonas fermentans was reclassified in a novel genus as *Actinotalea fermentans* based mainly on 16S rRNA gene phylogeny and the predominance of the quinone system menaquinone MK-10(H_4) (Yi et al., 2007) which is rare among bacteria.

Both phylogeny and quinone system distinguish the genus from *Cellulomonas* which exhibits menaquinone MK-9(H_4) as the major compound. Although *Actinotalea fermentans* was placed phylogenetically quite distant from *Cellulomonas* species, 16S rRNA gene sequence similarities (94.5–96.1%) with species of this genus suggest at least a closer relatedness than with other genera. This relatedness is supported by similar fatty acid profiles which consist mainly of branched acids and a significant proportion of the unbranched acid $C_{16:0}$ and by the peptidoglycan of *Actinotalea fermentans* consisting of the diagnostic diamino acid L-ornithine and an interpeptide bridge with D-aspartic acid which is also exhibited by some *Cellulomonas* species (Jones et al., 2005). On the other hand, adding *Actinotalea fermentans* to the family *Cellulomonadaceae* would increase the phenotypic heterogeneity within the family whose representatives share the characteristic menaquinone MK-9(H_4).

Five additional *Actinotalea* strains, as indicated by 16S rRNA gene sequence similarities higher than 96.8%, might be accessible from institutional culture collections: *Actinotalea* species GF, accession no. EU016408 (99.5%), isolated from a benzene-degrading, iron-reducing laboratory enrichment culture (Kunapuli et al., 2007); *Cellulomonas* species ANA-WS2, accession no. EU303275 (97.9%), isolated from a flood field; *Actinotalea fermentans* SAFR-046, AY167843, (97.2%), isolated from a spacecraft assembly facility; actinobacterium PB90-5, accession no. AJ229241 (97.0%), isolated from anoxic bulk soil of a flooded rice microcosm; and actinobacterium SOC A20(63), accession no. DQ628959 (96.9%), isolated from a subglacial bacterial community (Cheng and Foght, 2007).

Enrichment and isolation procedures

The type strain was isolated from an enrichment culture from a municipal dumping ground sample in basal medium* supplemented with 8% barley straw and, after autoclaving, with (per liter) 10 ml of sterile cysteine-hydrochloride solution (5.0%) and 10 ml of sterile sodium bicarbonate solution (8.0%); it was incubated under anaerobic conditions for five weeks. Samples from the enrichment were used to inoculate cellulose agar roll tubes [basal medium supplemented with 4.0% (w/v) ball-milled MN300 cellulose and 2.0% agar] and incubated according to the Hungate roll-tube technique (Hungate, 1969). After 2 weeks of incubation, colonies developing cleared zones of cellulose digestion were detected.

Pathogenicity. No reports exist which indicate a pathogenic potential of this organism.

Maintenance procedures

For maintenance, basal medium supplemented with 0.5% MN300 cellulose in 10 ml volumes under an O_2-free argon atmosphere is recommended (Bagnara et al., 1985).

Differentiation of the genus *Actinotalea* from other genera

The most useful trait for differentiation of the genus from other taxa is the quinone system consisting of the major menaquinone MK-10(H_4). This characteristic unambiguously differentiates the genus from the next closely related genera as indicated by 16S rRNA gene sequence similarities, including *Cellulomonas* and *Oerskovia* which both exhibit the major quinone menaquinone MK-9(H_4) (An et al., 2005; Brown et al., 2005a; Collins and Pascual, 2000; Elberson et al., 2000; Jones et al., 2005; Kang et al., 2007; Rivas et al., 2004; Stackebrandt et al., 2002a, 2002b). So far, MK-10(H_4) has only been reported to be the major quinone in certain species of the genus *Arcanobacterium* (Lehnen et al., 2006). Differentiation between *Actinotalea* and *Arcanobacterium* can be easily achieved by analysis of the fatty acid profile. *Actinotalea* exhibits a fatty acid profile in which branched acids predominate, whereas in *Arcanobacterium*, unbranched acids predominate.

List of species of the genus *Actinotalea*

1. **Actinotalea fermentans** (Bagnara, Toci, Gaudin and Belaich 1985) Yi, Schumann and Chun 2007, 155[VP] (*Cellulomonas fermentans* Bagnara, Toci, Gaudin and Belaich 1985, 506)

fer.men′tans. L. part. adj. *fermentans* fermenting.

The species exhibits the characteristics listed in the genus description. Size of the cells is 0.2–0.5 x 0.6–1.7 µm. Gram-behavior after staining is negative, but ultrastructure of the murein is Gram-positive. Colonies are white with an undulate margin, 2–3 mm in diameter. On cellulose agar, digestion extending from the periphery of the colony is observed. Optimum pH is 7.4, and growth is substantially reduced at pH lower than 7.0 or higher 8.0. Optimum growth is observed at 30–37°C, but no growth at 50°C. Nitrate is reduced, gelatin is liquefied, and NH_4 is produced from peptone. Acetyl methyl carbinol and indol are not produced. Catalase and urease are negative. Arabinose, cellulose, fructose, galactose, glucose, glycogen, lactose, maltose, mannose, mannitol, raffinose, starch, sucrose, trehalose, xylose, and xylan are used as a single source of carbon and energy, but asparagine, arbutin, glycerol, inulin, melibiose, melezitose, pectin, rhamnose, ribose, pyruvate, salicin, sorbitol, and urea are not. Does not grow under aerobic conditions with butanol, butyrate, citrate, ethanol, gluconate, lactate, propanol, propionate, or succinate, but it grows slowly with acetate. Growth is only slightly supported in the presence of yeast extract (0.05%) or Casamino acids (0.2%). Growth factors other than biotin and thiamin together are required and can be provided by 0.05% yeast extract. Products of fermentation are acetic acid, formic acid, ethanol, occasionally L-(+)-lactic acid and, in small amounts, CO_2 and succinic acid. Cell-wall sugars are glucose, rhamnose, and ribose.

DNA G+C content (mol%): 75.8 (T_m).

Type strain: M, ATCC 43279, CFBP 4259, CIP 103003, DSM 3133, JCM 9966, LMG 16154, NBRC 15517.

Sequence accession no. (16S rRNA gene): X79458, X83805.

*Basal medium composition: 2.21g/l K_2HPO_4, 1.50 g/l KH_2PO_4, 1.30 g/l $(NH_4)SO_4$, 0.10 g/l $MgCl_2 \cdot 6H_2O$, 0.02 g/l $CaCl_2 \cdot 2H_2O$, 0.25 ml $FeSO_4$ solution [0.5% (w/v)], 5g/l yeast extract, pH 7.4.

Genus III. *Incertae sedis* Demequina Yi, Schumann and Chun 2007, 154[VP]

Hans-Jürgen Busse

De.me.qui'na. N.L. fem. n. *Demequina* arbitrary name derived from demethylmenaquinone, an unusual quinone found in this organism.

Gram-stain-positive, strictly aerobic, and slightly halophilic. Oxidase negative, catalase positive and acid-fast negative. Non-spore-forming. Cells are nonmotile rods with round ends. The only isoprenoid quinone is **demethylmenaquinone DMK-9(H_4)**. The peptidoglycan contains the **diagnostic diamino acid L-ornithine** and alanine, glycine, serine, D-glutamate, and aspartate. **Cross-linkage** is of **A-type.** D-Glutamate represents the N-terminus of the interpeptide bridge. Predominant **cellular fatty acids** are of the **anteiso-branched and straight-chain types**. **Major polar lipids** are **phosphatidylinositol, diphosphatidylglycerol**, and an **unknown phospholipid**. Phylogenetically, the genus is affiliated to the order *Micrococcales*.

DNA G+C content (mol%): 67.

Type species: **Demequina aestuarii** Yi, Schumann and Chun 2007, 154[VP].

Further descriptive information

The genus *Demequina* consist so far only of a single species, *Demequina aestuarii*, and its description is based on a single strain (Yi et al., 2007). The strain was isolated from a tidal flat sediment sample from Ganghwa Island, South Korea. Phylogenetically, the species was shown to branch close to the origin of the *Intrasporangiaceae* clade. However, this branching is not supported by significant bootstrap values. The uncertainty of the phylogenetic placement is also supported by similar 16S rRNA gene sequence similarities (94.0–94.2%) with the type species of *Actinotalea* and representatives of the *Sanguibacteraceae*, *Cellumonadaceae*, and *Intrasporangiaceae*. *Demequina aestuarii* exhibits a fatty acid profile in which methyl-branched acids and significant amounts of $C_{16:0}$ predominate. Similar fatty acids have been only reported for *Actinotalea fermentans* and *Cellulomonas* species. The presence of the diagnostic diamino acid L-ornithine in the cell wall clearly distinguishes *Demequina aestuarii* from *Sanguibacteracea* which were reported to contain L-lysine (Fernández-Garayzábal et al., 1995; Huang et al., 2005; Pascual et al., 1996). The other two related families are heterogeneous concerning this trait. Taxa within *Cellulomonadaceae* are characterized either by the presence of L-ornithine or L-lysine (An et al., 2005; Brown et al., 2005a; Collins and Pascual, 2000; Elberson et al., 2000; Jones et al., 2005; Kang et al., 2007; Rivas et al., 2004; Stackebrandt et al., 2002a, 2002b), and *Intrasporangiaceae* (Groth et al., 1999, 2001; Hanada et al., 2002) have been reported to be comprised of taxa which exhibit the presence of L-ornithine or isomers of diaminopimelic acid as the diagnostic diamino acid in the peptidoglycan. The quinone system consisting of the major compound demethylmenaquinone DMK-9(H_4) has not been reported for any species of the *Intrasporangiaceae*, *Sanguibacteraceae*, or *Cellulomonadaceae*, nor for any other taxon of the *Actinobacteria*. Hence, placement of *Demequina aestuarii* in a certain family is not supported by chemotaxonomic characteristics and would create more phenotypic heterogeneity in each family. However, it would be highly desirable if other potential members of the genus (see below) would be examined to determine whether they share this trait.

In addition to the single described species of the genus *Demequina*, members of the genus might be available from institutional culture collections, as can be concluded from 16S rRNA gene sequence entries in gene banks which are seen to share more than 95.0% 16S rRNA gene sequence similarity with the type strain of *Demequina aestuarii*: *Cellulomonas* species KAR82, accession no. EF451710 (97.0%), isolated from Arctic permafrost soil from Spitsbergen, Northern Norway (Hansen et al., 2007); *Cellulomonas* species NP4, accession no. EU196315 (96.0%), isolated from cold saline (7.5% salt) sulfidic spring, Canadian High Arctic; *Sanguibacter* species NH20, accession no. EU109730 (95.9%), isolated from tidal paddy soil; actinobacterium A11, accession no. AB302329 (95.6%), isolated from Indonesian seawater (Harwati et al., 2007); and *Cellulomonas* species F11, accession no. EU697083 (95.2%), isolated from mangrove sediments in Fujian, Fugong, south of the Jiulong River estuary (China). Three additional gene bank entries of bacterial strains held at the IFO culture collection were found with high sequence similarities to *Demequina aestuarii*. Recently, strains from this collection were transferred to NITE Biological Resource Center (NBRC) keeping the IFO numbers. However, it is not clear whether these strains are yet available from NBRC because they could not be found in the catalog of this collection. These strains are: *Cellulomonas* species IFO 16240, accession no. AB023361 (96.7%); *Cellulomonas* species IFO 16241, accession no. AB023362 (96.5%); and *Cellulomonas* species IFO 16246, accession no. AB023367 (96.3%).

Enrichment and isolation procedures

Demequina aestuarii can be isolated from sediment by standard dilution plating on marine agar (Difco 2216).

Pathogenicity. No reports concerning pathogenic potential of *Demequina aestuarii* can be found in literature.

Maintenance procedures

Demequina aestuarii can be maintained as a glycerol suspension (20%, w/v) at −80°C.

Differentiation of the genus *Demequina* from other genera

The most striking characteristic of *Demequina aestuarii* is the quinone system consisting demethylmenaquinone DMK-9(H_4) as its only component. No other actinobacterial taxon has been reported to share this quinone system, hence it can be considered as a diagnostic trait of the species and perhaps for the genus as well.

List of species of the genus *Demequina*

1. **Demequina aestuarii** Yi, Schumann and Chun 2007, 154[VP]

ae.stu.a′ri.i. L. gen. n. *aestuarii* of a tidal flat, isolated from tidal flat sediment.

In addition to the characteristics listed in the genus description the species exhibits the following properties: size of cells is 0.25–0.35 x 0.60–1.20 µm. Growth occurs at pH 6–11 (optimum, pH 7), in 0–12% (w/v) NaCl (optimum, 2–4 %), and at 5–35°C (optimum, 33.5°C). Minimum doubling time is 6.4 h. Extended incubation (up to 15 d) is required at 5°C. Growth occurs on marine agar (Difco 2216), ISP medium No. 3 (Difco) supplemented with sea salts, ISP medium No. 4 (Difco) supplemented with sea salts, and PYGV (Staley, 1968) supplemented with sea salts, but not on Oatmeal agar supplemented with sea salts. Colonies on marine agar at 30°C are yellow, translucent, and circular, with entire margins, approximately 0.2 mm in diameter after 2 d, with a maximum diameter of 3–4 mm after 7 d. Negative for arginine dihydrolase and urease activities. Positive for β-galactosidase activity. Nitrate is not reduced to nitrite. Does not produce H_2S. Acid is not produced from glucose, nor indole from tryptophan. Decomposes carboxymethylcellulose, DNA, and esculin, but not adenine, alginate, casein, chitin, gelatin, hypoxanthine, starch, Tween 80, tyrosine, or xanthine. On the basis of the API ZYM system, the organism is positive for leucine arylamidase, β-galactosidase, α-glucosidase, and β-glucosidase; weakly positive for naphthol-AS-BI-phosphohydrolase; negative for alkaline phosphatase, esterase (C4), esterase lipase (C8), lipase (C14), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, acid phosphatase, α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, mannosidase, and fucosidase. Utilizes D-cellobiose, D-fructose, D-galactose, D-glucose, D-mannitol, D-mannose, D-salicin, D-trehalose, D-xylose, glycerol, L-arabinose, and sucrose as a sole carbon source. Utilization of lactose is weak. Does not utilize acetamide, acetate, benzoate, citrate, D-raffinose, D-ribose, D-sorbitol, ethanol, glycine, inositol, inulin, 2-propanol, L-arginine, L-ascorbate, L-asparagine, L-lysine, L-ornithine, L-rhamnose, *N*-acetylglucosamine, polyethylene glycol, salicylate, succinate, tartrate, or thiamine. Major fatty acids are $C_{15:0}$ anteiso, $C_{17:0}$ anteiso, $C_{16:0}$, and $C_{15:1}$ anteiso (relative amounts 10–50%); $C_{16:0}$ iso, $C_{15:0}$, and $C_{15:0}$ iso are found in moderate amounts (3–10%)

Source: a tidal flat sediment sample from Ganghwa Island, South Korea.

DNA G+C content (mol%): 67 (HPLC).

Type strain: JC2054, IMSNU 14027, JCM 12123, KCTC 9919.

Sequence accession no. (16S rRNA gene): DQ010160.

Genus IV. **Oerskovia** Prauser, Lechevalier and Lechevalier 1970, 534[AL] emend. Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1108

Erko Stackebrandt and Peter Schumann

O.er.sko′vi.a. N.L. fem. n. *Oerskovia* in honor of J. Ørskov who first described this organism.

Extensively branching vegetative hyphae (~0.5 µm in diameter) growing on the surface of and penetrating into the agar, **which break up into motile or nonmotile rod-like elements**. Growth appears bacteroid in smears. No aerial mycelium. Motile or nonmotile. Gram-stain-positive; catalase-positive; oxidase-positive. **Aerobic to facultatively anaerobic**; strict aerobic strains may occur. Major fatty acids are $C_{15:0}$ anteiso, and $C_{16:0}$; $C_{15:0}$ iso, $C_{14:0}$, and $C_{17:0}$ anteiso occur in smaller amounts. **Major isoprenoid quinone is MK-9(H_4). Diamino acid of peptidoglycan is L-lysine; the interpeptide bridge consists of either L-Thr←D-Asp or L-Thr←D-Glu**. Muramic acid residues are acetylated. Major polar lipids are phosphatidylglycerol, diphosphatidylglycerol, and phosphatidylinositol. Widely distributed in soil.

DNA G+C content (mol%): 70.5–75.0.

Type species: **Oerskovia turbata** (Erikson 1954) Prauser, Lechevalier and Lechevalier 1970, 534[AL] emend. Lechevalier 1972, 263 emend. Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1109 (*Nocardia turbata* Erikson 1954).

Further descriptive information

Erikson (1954) described "Oerskov's motile nocardia, strain 27", which was first reported by Ørskov (1938), as *Nocardia turbata*. The rational for the reclassification of this species as the type species of the new genus *Oerskovia*, *Oerskovia turbata* (Prauser et al., 1970), was based on evidence that members of this species were phenetically different from strains of *Nocardia* of the *asteroides–farcinica* type (Jones and Bradley, 1964; Prauser, 1967; Sukapure et al., 1970). This species differs significantly from authentic *Nocardia* strains by exhibiting lysine as the diagnostic diamino acid of the peptidoglycan rather than *meso*-diaminopimelic acid as found in nocardiae. Many strains of the species are motile by flagellation of fragmented hyphal parts (Sukapure et al., 1970) (named motile "spores" by Higgins et al., 1967). The genus was emended by Lechevalier (1972) based on the capability of the species to grow anaerobically on trypticase-soy agar (one of 15 media tested), to metabolize glucose oxidatively and fermentatively, and because it is catalase negative when grown under anaerobic conditions.

Oerskoviae were randomly and rarely isolated from various types of soils from different geographical regions, composts, decaying plant materials, and occasionally from various clinical specimens (Reller et al., 1975; Sottnek et al., 1977; Cruickshank et al., 1979; see below). *Oerskovia enterophila* constitutes the major part of the actinomycete microflora of the intestines and feces of litter-inhabiting millipedes, e.g. *Chromatoiulus projectus* (Dzingov et al., 1982; Jáger et al., 1983; Szabó et al., 1986). This species also occurs in the feces of the cave-inhabiting blind isopode, *Mesoniscus graniger* (Bodnar et al., 1989). A large homogeneous

population of facultatively anaerobic *Oerskovia*-type nocardioforms was also found in the gut contents of adult specimens of the common earthworm *Lumbricus polyphemus* (Ravasz et al., 1987; Szabó et al., 1986). None of these oerskoviae could be isolated from the surrounding feeding habitats of the animals, nor did they survive in the natural soil and litter habitat (Márialigeti et al., 1985). On the other hand, 13 out of 311 culturable cellulolytic bacterial isolates from soil of an agricultural encatchment were closely related (99.6% 16S rDNA gene sequence similarity) to *Oerskovia* (*Promicromonospora*) *enterophila* (Ulrich and Wirth, 1999).

Pathogenicity. *Oerskovia* strains have been implicated as agents of disease since the first report of Reller et al. (1975). Isolates from blood, heart tissues and heart valves have been identified as *Oerskovia turbata* strains while *Oerskovia xanthineolytica* strains have been isolated from blood, cerebrospinal fluid, sputum, urine, and wounds (Sottnek et al., 1977). *Oerskovia* strains have been reported to cause cholecystitis (Thomas et al., 2007), endocarditis (Reller et al., 1975; Urbina et al., 2003), endophthalmitis (Hussain et al., 1987), keratitis (Shah et al., 1996), meningitis (Kailath et al., 1988), peritonitis (Lujan-Zilbermann et al., 1999; Rihs et al., 1990), pyonephritis (Cruickshank et al., 1979), and different types of bacteremia (LeProwse et al., 1989; Niamut et al., 2003). Successful antibiotic therapy has been achieved with vancomycin in several cases of foreign-body-associated infections involving catheters or prosthetic joints (Harrington et al., 1996; Rihs et al., 1990). The unambiguous identification of *Oerskovia* strains requires a polyphasic strategy, hence reports on *Oerskovia* infections diagnosed only by using commercial, phenotype-based diagnostic test systems are difficult to evaluate. Several isolates from clinical specimens identified as *Oerskovia turbata* were reclassified as *Cellulosimicrobium funkei* (Brown et al., 2006).

Taxonomic comments

The discovery that the genera *Cellulomonas* and *Oerskovia* were highly related phylogenetically led to the latter becoming a synonym of the former (Stackebrandt et al., 1982) and the consequential reclassification of *Oerskovia turbata* as *Cellulomonas turbata*. However, the distinctiveness of *Cellulomonas turbata* from other *Cellulomonas* species was evident even at the time of unification, as authentic cellulomonads were not susceptible to *Oerskovia* phages (Prauser, 1986) and showed differences in peptidoglycan composition and the ability to form mycelia. The emphasis at the time of unification was placed on the phylogenetic position of strains rather than on the presence of distinctly different chemotaxonomic properties (Stackebrandt and Prauser, 1991b). As more species of *Cellulomonas* were described, members of the genus *Oerskovia* were pushed towards the periphery of the *Cellulomonas* phylogenetic tree. The application of different tree-making algorithms to the 16S rRNA gene sequence dataset composed of members of the suborder *Micrococcineae* (since elevated to order *Micrococcales* in the roadmap to the present volume) showed that *Cellulomonas* [*Oerskovia*] *turbata* and its relatives branched close to the root of the *Cellulomonas* tree in most analyses, though the branching was never supported by bootstrap values that would have signaled statistically significant differences. Nevertheless, the phylogenetic position of *Cellulomonas* [*Oerskovia*] *turbata* and the notion that there was a high correlation between phylogenetic position and chemotaxonomic uniqueness among actinobacterial genera (Stackebrandt and Schumann, 2000a) led to the re-establishment of the genus *Oerskovia* (Stackebrandt et al., 2002a). These workers also transferred *Promicromonospora enterophila* to the genus *Oerskovia* as *Oerskovia enterophila* on the basis of phylogenetic (99.6% 16S rRNA gene sequence similarity with *Oerskovia turbata*), chemotaxonomic, and physiological data (Jáger et al., 1983) as well as on phage susceptibility studies (Prauser, 1986). Two new *Oerkovia* species, *Oerkovia jenensis* and *Oerkovia paurometabola*, were also described in this study to accommodate strains which, until then, had been recognized as either *Cellulomonas turbata* or *Promicromonospora enterophila*.

The description of additional *Cellulomonas* species led to the genus *Oerskovia* being placed back into the radiation of *Cellulomonas* species, though low bootstrap values indicate the tentativeness of this relationship (Figure 151). The high phylogenetic relatedness found between the four *Oerskovia* species is reflected by moderately high DNA–DNA reassociation values which range 55–75% similarity. *Oerskovia paurometabola* and *Oerskovia jenensis* are particularly close neighbors, as strains of these species share 64–75% DNA–DNA similarity (Stackebrandt et al., 2002a).

Oerskovia xanthineolytica (Lechevalier, 1972) has also had a checkered taxonomic history. When the type species *Oerskovia turbata* was transferred to the genus *Cellulomonas* as *Cellulomonas turbata*, *Oerskovia xanthineolytica*, the second species in the genus *Oerskovia*, was not described as the type species of the genus, hence this species stayed without genus affiliation. Stackebrandt and Kandler (1980a) proposed *Oerskovia xanthineolytica*, *Nocardia cellulans*, and some other taxa as subjective synonyms of *Cellulomonas cartae* which was described for the then non-validly published species "*Cellulomonas cartalyticum*". However, *Nocardia cellulans* Metcalf and Brown (1957) had priority over *Cellulomonas cartae*, hence this assemblage of strains was reclassified as *Cellulomonas cellulans* (Stackebrandt and Keddie, 1986). Besides *Cellulomonas cartae* and *Oerskovia xanthineolytica*, other taxa included in this species were "*Arthrobacter luteus*" (Kaneko et al., 1969), *Brevibacterium fermentans* (Chatelain and Second, 1966), *Brevibacterium lyticum* (Takayama et al., 1960), and "*Corynebacterium manihot*" (Collard, 1963). These organisms were considered to belong to the same species as they shared the peptidoglycan type L-Lys←D-Ser←D-Asp (Seidl et al., 1980; for additional references, see below), were susceptible to *Oerskovia* phages (particularly to those active against *Oerskovia xanthineolytica*; Prauser, 1984, 1986), and were found to be similar based on numerical taxonomic data (Jones, 1975; Seiler, 1983; Seiler et al., 1977). In addition, high DNA–DNA relatedness values were obtained for *Brevibacterium fermentans*, *Cellulomonas cellulans*, "*Corynebacterium manihot*", and *Oerskovia xanthineolytica* (60–68%; Stackebrandt et al., 1980; Prauser, 1986), while *Cellulomonas cartae* and *Nocardia cellulans* were found to be closely related based on 16S rRNA cataloging data (Stackebrandt et al., 1980). *Cellulomonas cellulans* (including the synonym *Oerskovia xanthineolytica*) has recently been reclassified as *Cellulosimicrobium cellulans* (Schumann et al., 2001).

Isolation and enrichment

Oerskoviae, like many other soil bacteria, grow on a wide range of media. The main problem in their isolation is the exclusion

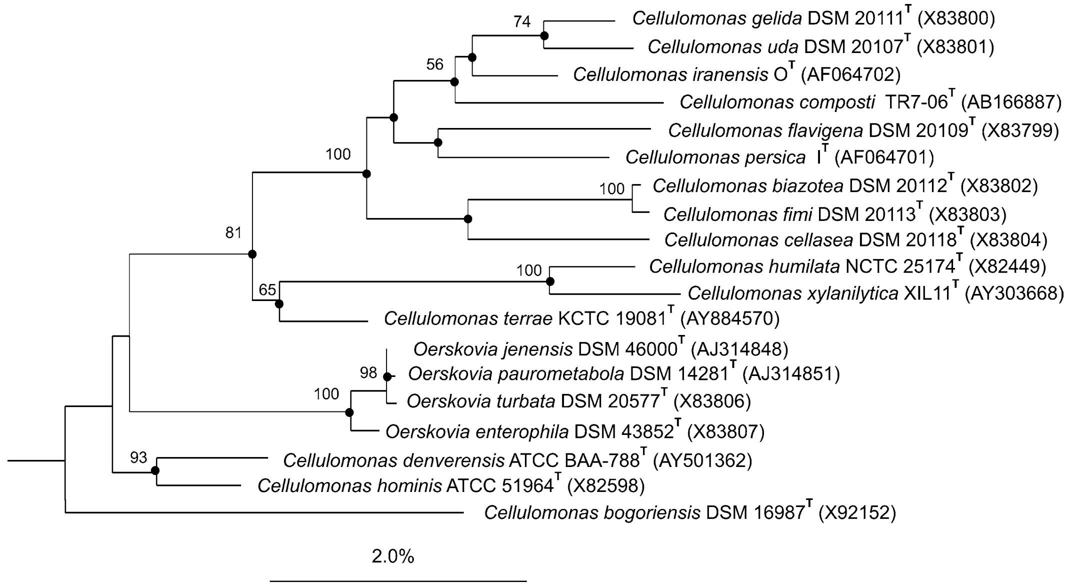

FIGURE 151. Neighbor-joining tree based on almost complete 16S rRNA gene sequences showing relationships between type strains of *Oerskovia* and *Cellulomonas*. Dots at branching points indicate that the same topologies were recovered by maximum likelihood analysis (Felsenstein, 1981). Numbers at branching points are per cent bootstrap values (1000 resamplings) (only values of 60% and above are shown). Members of the order *Micrococcales* were used to root the tree.

of contaminants that can cover large areas of isolation plates, e.g. swarming bacilli, pseudomonads, and hyphal fungi, as well as the suppression of streptomycetes, which may be confused at first sight with young stages on the isolation plates and which may antagonize oerskoviae. Procedures and media recommended for the isolation of *Promicromonospora* strains (Stackebrandt and Prauser, 1991b) can be used to isolate oerskoviae. Tapwater agar (1.5% crude agar in tap water; Lechevalier and Lechevalier, 1986) has been used to isolate oerskoviae.

Maintenance procedures

Serial transfers on nutrient agar at 4-week intervals followed by maintenance at 4°C are recommended for maintaining oerskoviae. Storage of cells as 20% (w/v) glycerol suspensions at −20°C and at −80°C is a suitable preservation method. Long-term preservation methods include freeze drying in skim milk and maintenance in liquid nitrogen at −196°C.

Differentiation of *Oerskovia* from related genera

The most reliable way of placing an unidentified strain into the genus *Oerskovia* is to determine its 16S rRNA gene sequence and peptidoglycan type. In addition, *Oerskovia* strains are characterized by MK-9(H_4) as the predominant menaquinone, by a phospholipid pattern consisting of phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and three unidentified phospholipids, and by an A4α peptidoglycan type in which the amino acid moiety at position 3 of the peptide side chain consists of lysine and the interpeptide bridge is composed of threonine and either D-aspartic acid (L-Lys←L-Thr←D-Asp) or D-glutamic acid (L-Lys←L-Thr←D-Glu) (Seidl et al., 1980). In contrast, strains of *Cellulomonas* possess L-ornithine at position 3 of the side chain and a single dicarboxylic amino acid (either D-aspartic acid or D-glutamic acid) defines the interpeptide bridge. The main fatty acids of oerskoviae are similar to those of phylogenetically close taxa.

A set of phages has been proposed as specific to the genus *Oerskovia* (Prauser, 1984, 1986; Prauser and Falta, 1968; Stackebrandt and Prauser, 1991b). The reclassification of *Oerskovia xanthineolytica* first as *Cellulomonas cellulans* and then as *Cellulosimicrobium cellulans* means that phages O5 (specific for DSM 49112) and O13 (for DSM 49139) have to be removed from the *Oerskovia* phage set. Although studies on the phage susceptibility of members of the family *Cellulomonadaceae* have not been performed recently, it seems reasonable to restrict the set of *Oerskovia*-specific phages to O6 (DSM 49111) (host *Oerskovia turbata* DSM 20577^T), O2 (DSM 49109) (host *Oerskovia turbata* DSM 43878), and O3 (DSM 49138) (host *Oerskovia jenensis* DSM 46000^T). Phages have not been described for the other *Oerskovia* species.

Differentiation of the species of the genus *Oerskovia*

Oerskovia enterophila DSM 43852^T utilizes a broad range of Biolog compounds (76 out of 95 substrates metabolized), whereas *Oerskovia paurometabola* DSM 14281^T mainly gives negative results towards the Biolog substrate panel (28 out of 95 positive). *Oerskovia jenensis* and *Oerskovia turbata* are metabolically similar (Stackebrandt et al., 2002a). Phenotypic properties that can be used to differentiate between *Oerskovia* species are shown in Table 116. *Oerskovia turbata* possesses the peptidoglycan type L-Lys←L-Thr←D-Asp, while the other members of the genus are defined by the L-Lys←L-Thr←D-Glu peptidoglycan type. *Oerskovia* strains fall into species specific clusters based on RiboPrint patterns generated by using the restriction enzyme *Pst*I (Figure 152; Stackebrandt et al., 2002a).

TABLE 116. Characteristics differentiating phenotypic properties of *Oerskovia* species as determined by using API Coryne kits[a,b]

Characteristic	*O. turbata*	*O. jenensis*	*O. enterophila*	*O. paurometabola*
β-Galactosidase	+	w	+	−
Gelatin hydrolysis	+	−	−	−
Glycogen fermentation	v	+	+	+
Pyrazinamidase	−	−	+	−
Urease	−	v	+	+

[a]Symbols: +, >85% positive; -, 0–15% positive; w, weak reaction; v, variable.

[b]All strains were positive in the following reactions: *N*-acetyl-β-glucosidase, catalase, oxidase, α- and β-glucosidase, nitrate reduction, pyrazimidase, and in fermenting glucose, maltose, ribose saccharose, and xylose. They were negative for β-glucuronidase, pyrrolidonyl arylamidase, and in fermenting lactose and mannitol. All strains utilized the following Biolog GP substrates: *N*-acetylglucosamine, adenosine, adenosine-5′-monophosphate, β-cyclodextrin, 2-deoxyadenosine, dextrin, D-gluconic acid, α-D-glucose, glycogen, glycerol, inosine, maltose, maltotriose, mannose, methyl-pyruvate, ribose, salicin, sucrose, thymidine, trehalose, turanose, Tween 40, uridine, and D-xylose but not for: L-alanine, L-D-alanine, alaninamide, L-alanyl-glycine, D-arabitol, glucose 1-phosphate, glucose 6-phosphate, inulin, *p*-hydroxyphenyl acetic acid, α-ketoglutaric acid, and melezitose.

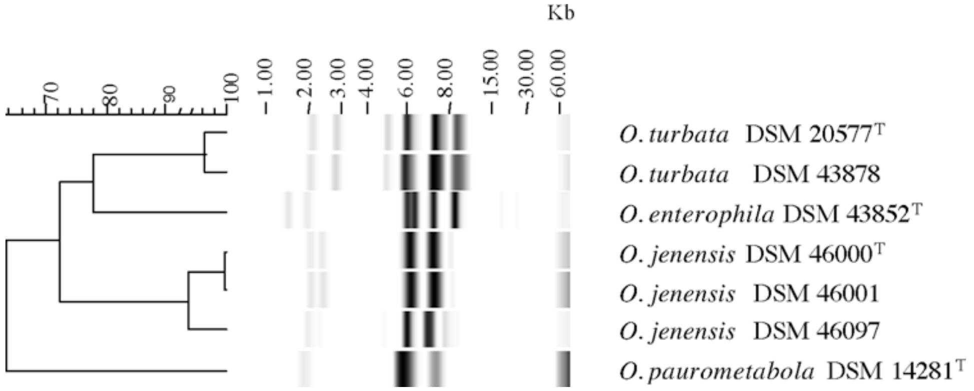

FIGURE 152. RiboPrint pattern of strains of the genus *Oerskovia* generated with *Pst*I. The dendrogram (Pearson correlation) was generated using BioNumerics software (Applied Maths, Kortrijk, Belgium).

List of species of the genus *Oerskovia*

1. **Oerskovia turbata** (Erikson 1954) Prauser, Lechevalier and Lechevalier 1970, 534[AL] emend. Lechevalier 1972, 263; emend. Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1109 (*Nocardia turbata* Erikson 1954)

tur.ba′ta L. fem. adj. *turbata* agitated.

Extensively branching vegetative hyphae fragment into motile rod-like elements which are usually monotrichous when small and peritrichous when long (~0.4–1.1 µm). Colonies on CASO (Difco) are lemon yellow and 0.2–0.4 mm in diameter at 28°C after 2 d. Nitrite is produced from nitrate. Casein, gelatin, and starch are hydrolyzed. Catalase positive. Not acid fast. The type strain is aerobic to facultatively anaerobic. Mesophilic. Isolated from soil. Acid is produced from arabinose, cellobiose, dextrin, fructose, galactose, glucose, glycerol, glycogen, α-methyl-D-glucose, β-methyl-D-xyloside, lactose, maltose, mannose, salicin, sucrose, trehalose, and xylose but not from adonitol or inositol. Acetate, lactate, and pyruvate are used as sole carbon sources, but benzoate, succinate, tartrate, and tyrosine are not. The following tests are variable (percent positive strains): degradation of hypoxanthine (37%), xanthine (37%), use of citrate (37%), and propionate (88%) as sole carbon sources and acid production from mannitol (12%), melibiose (37%), raffinose (25%), rhamnose (12%), sorbitol (25%), and sorbose (12%). In addition to the physiological reactions shown in Table 116 the following Biolog substrates are utilized: α-acetyl mannosamine, amygdalin, arbutin, cellobiose, D-fructose, D-galactose, gentobiose, D-lactic acid methylester, L-lactic acid, α-D-lactose, mannan, D-melibiose, α-methyl-D-galactoside, and sodium, acetic. Peptidoglycan type is L-Lys←L-Thr←D-Asp. $C_{15:0}$ anteiso is the major fatty acid (>40%); $C_{15:0}$ iso, $C_{16:0}$, $C_{14:0}$, $C_{16:0}$ iso, and $C_{17:0}$ anteiso occur in smaller amounts (<5–20%).

Source: soil.

DNA G+C content (mol%): 71–75 (T_m).

Type strain: 891, Ørskov strain 27, ATCC 25835, CFBP 4266, CIP 100331, DSM 20577, NBRC 15015, JCM 3160, LMG 4072, NCIMB 10587, NCTC 11973, NRRL B-8019, VKM Ac-1024.

Sequence accession no. (16S rRNA gene): X79454, X83806.

2. **Oerskovia enterophila** (Jáger, Márialigeti, Hauck and Barabás 1983) Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1110[VP] (*Promicromonospora enterophila* Jáger, Márialigeti, Hauck and Barabás 1983, 530)

en.ter.o′phi.la. Gr. n. *enteron* intestine; Gr. adj. *philos, ê, on* loving; N.L. fem. adj. *enterophila* gut-loving.

Gram-stain-positive, non-acid-fast, facultatively anaerobic organism with branching vegetative hyphae. Aerial mycelium absent. Substrate hyphae fragment into nonmotile bacillary and coccoid or sporelike elements. In general, colonies are glistening, soft, pasty, and cream yellow in color. On CASO agar (DIFCO) they are 0.3–0.5 mm in diameter at 28°C after 2 d. On starch-yeast extract media rough, wrinkled, dull colony variants may occur. Does not form water-soluble diffusible pigments or melanin pigments. Growth occurs at pH 3.0, in 5% NaCl, and at 32°C. Cellulose is not degraded. Indole and Voges–Proskauer tests are negative. Does not degrade hypoxanthine, ribonucleic acid, tyrosine, Tween 80, or xanthine. Reaction for β-glucosidase (esculin) is positive in the API "Coryne" substrate panel but negative according to Jáger et al. (1983). Glucose is metabolized both oxidatively and fermentatively. Dextrin, lactose, maltose, mannose, sucrose, salicin, trehalose, and xylose used as sole carbon sources, but adonitol, dulcitol, inositol, inulin, mannitol, melibiose, melezitose, raffinose, rhamnose, sorbitol, and sorbose are not. In addition to the physiological reactions shown in Table 116, the following Biolog substrates are utilized: α-acetyl mannosamine, amygdalin, arbutin, L-asparagine, lactic acid, cellobiose, D-fructose, fructose-6-phosphate, DL-fucose, D-galactose, D-galacturonic acid, gentobiose, α-hydroxybutyric acid, γ- hydroxybutyric acid, lactamide, *meso*-inositol, D-lactic acid methylester, α-D-lactose, D-malic acid, mannan, D-melibiose, α-methyl-D-galactoside, sedoheptulosan, sodium acetate, and stachyose. Susceptible to cephalosporine (10 μg ml), pristinamycin (10 μg ml), spiramycin (30 μg ml), and vancomycin (50 μg ml), but resistant to nalidixic acid (30 μg ml), nitrofurantoin (300 μg ml), and nystatin (100 IU). The peptidoglycan is of the A4α type, variation L-Lys←L-Thr←D-Glu. $C_{15:0}$ anteiso is the major fatty acid (~51%); $C_{15:0}$ iso, $C_{16:0}$, $C_{14:0}$, $C_{16:0}$ iso, and $C_{17:0}$ anteiso occur in smaller amounts (<4–17%). The cell-wall sugars are fucose, mannose, and rhamnose.

DNA G+C content (mol%): 71 (T_m).

Type strain: DFA-19, ATCC 35307, DSM 43852, HMGB B1078, NBRC 14295, JCM 7350, NRRL B-16223.

Sequence accession no. (16S rRNA gene): X83807.

3. **Oerskovia jenensis** Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1110[VP]

je.nen′sis N.L. fem. adj. *jenensis* pertaining to Jena, Germany.

Gram-stain-positive, non-acid-fast, facultatively anaerobic organism with branching vegetative hyphae. Aerial mycelium absent. Substrate hyphae fragment into motile bacillary and coccoid or sporelike elements. On CASO agar (DIFCO) colonies are cream-yellow, 0.2–0.4 or 0.5–0.7 mm in diameter at 28°C after 2 d. Does not produce water-soluble diffusible pigments or melanin. Glucose is metabolized both oxidatively and facultative fermentatively. In addition to the physiological reactions indicated in Table 116 the following Biolog substrates are utilized: α-acetyl mannosamine, amygdalin, arbutin, cellobiose, D-fructose, D-galactose, gentobiose, D-lactic acid methylester, L-lactic acid, mannan, D-melibiose, α-methyl-D-galactoside, and sodium acetate. The peptidoglycan is of the A4 α type, variation L-Lys←L-Thr←D-Glu. The major fatty acid is $C_{15:0}$ anteiso (54%); $C_{16:0}$, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{14:0}$ (8.0–15%) occur in smaller amounts.

Sequence accession no. (16S rRNA gene): AJ314848.

4. **Oerskovia paurometabola** Stackebrandt, Breymann, Steiner, Prauser, Weiss and Schumann 2002a, 1110[VP]

pau.ro.me.ta′bo.la. Gr. adj. *pauros* little; Gr. adj. *metabolos* changeable; N.L. fem. adj. *paurometabola* producing little change.

Gram-stain-positive, non-acid-fast, facultatively anaerobic organism with branching vegetative hyphae. Aerial mycelium absent. Substrate hyphae fragment into motile bacillary and coccoid or sporelike elements. On CASO agar (DIFCO) colonies are cream-yellow, 0.5–0.6 mm in diameter at 28°C after 2 d. Does not form water-soluble diffusible pigments or melanin pigments. Glucose is metabolized both oxidatively and facultative fermentatively. Additional physiological reactions are indicated in Table 116. The peptidoglycan is of the A4 α type, variation L-Lys←L-Thr←D-Glu. Major fatty acid is $C_{15:0}$ anteiso (58%); $C_{16:0}$, $C_{17:0}$ anteiso, $C_{15:0}$ iso, and $C_{14:0}$ (8.0–18%) occur in smaller amounts.

Type strain: CCUG 47105, DSM 14281, JCM 11755, LMG 20385.

Sequence accession no. (16S rRNA gene): AJ314851.

Genus V. **Tropheryma** La Scola, Fenollar, Fournier, Altwegg, Mallet and Raoult 2001, 1478[VP]

Matthias Maiwald and David A. Relman

Tro.phe.ry′ma. Gr. n. *trophê* nourishment, food; Gr. neut. n. *eruma* fence, a defence against, barrier; N.L. fem. (*sic*) n. *Tropheryma* barrier to nourishment, so named because it causes malabsorption.

Straight, regular, small rods, generally 0.2–0.25 × 1.0–2.5 μm. Forms chains or cords in co-culture with human fibroblasts (La Scola et al., 2001; Maiwald et al., 2003b). Stains inconsistently Gram-stain-positive in infected human tissues (Dobbins, 1987) and Gram-stain-negative in culture (La Scola et al., 2001). Ziehl–Neelsen stain (acid-fastness) is negative. Periodic acid-Schiff (PAS) stain is positive (red color). **Does not grow in standard microbiological media**; growth in laboratory animals has not been described. Grows in tissue culture medium in co-culture with human fibroblasts (La Scola et al., 2001), as well as axenically in tissue culture medium supplemented with extra amino acids (Renesto et al., 2003). Intact cells in culture are

observed in intra- and extracellular locations. Grows at **37°C** in a **5% carbon dioxide** atmosphere; anaerobic or completely aerobic growth unknown. **Nonmotile**. Extremely **slow growth**; estimated bacterial generation time in culture between 28 and 96 h. When viewed by electron microscopy in infected human tissues, bacterial cells are surrounded by an outer membrane with symmetrical leaflets (Silva et al., 1985). Due to a lack of measurable biochemical characteristics, DNA sequence analysis is the most suitable technique for identification; commonly used genetic loci are 16S rRNA gene and 16S–23S rRNA intergenic spacer (accession no. X99636). *Tropheryma whipplei*, the etiologic agent of Whipple's disease, is the only species in the genus. The only naturally infected hosts are humans.

DNA G+C content (mol%): 46 (genome sequence).

Type species: **Tropheryma whipplei** La Scola, Fenollar, Fournier, Altwegg and Raoult 2001, 1478[VP].

Further descriptive information

Phylogeny. Phylogenetic information from the Whipple's disease bacterium was first obtained via broad-range 16S rDNA PCR and sequencing directly from infected human tissue, in the absence of any cultivated strain (Relman et al., 1992; Wilson et al., 1991). A phylogenetic placement within the actinomycetes (phylum *Actinobacteria*, class *Actinobacteria*) was established, and the organism was provisionally named "*Tropheryma whippelii*" (Relman et al., 1992). A more detailed phylogenetic analysis (Maiwald et al., 1996) established an intermediate position between the family *Cellulomonadaceae* and a cluster composed of actinomycetes with group B peptidoglycan (Figure 153). The highest 16S rDNA sequence similarities were found to the species *Leifsonia aquatica* (previously "*Corynebacterium aquaticum*," with group B peptidoglycan) and *Cellulomonas cellasea* (with group A peptidoglycan), both at 91.6%. However, with this level of similarity to its closest known relatives, the relationships of *Tropheryma whipplei* to any other known bacteria are quite distant. The placement of *Tropheryma whipplei* within the actinomycetes (phylum *Actinobacteria*) was confirmed on the basis of 23S rRNA, 5S rRNA, DNA-dependent RNA polymerase (*rpoB*), 65 kDa heat-shock protein (*groEL2*), elongation factor Tu (*tuf*), ATPase beta subunit (*atpD*), and RNase P RNA (*rnpb*) gene sequences (Maiwald et al., 2000, 2003a).

Cell morphology, cell-wall composition, and fine structure. Multiple electron-microscopic studies, summarized by Dobbins (1987), showed a uniform appearance of bacteria in tissues of patients with Whipple's disease, before the availability of cultures. The bacteria are small, rod-shaped, measuring approximately 0.2–0.25 × 1.0–2.5 µm. In human tissue, intact bacteria are found in intra- and extracellular locations; intracellular forms are also seen in various stages of degradation. Dividing bacterial shapes appear to be more commonly located extracellularly (Silva et al., 1985). In co-culture with human fibroblasts, the bacteria are arranged in chains (Figure 154) or cords (Maiwald et al., 2003b); the cords are also described as "rope-like structures" (La Scola et al., 2001). The bacteria are positively stained by PAS reagent, by acridine orange, by YO-PRO nucleic acid stain, and by specific fluorescently labeled human and mouse antibodies (La Scola et al., 2001; Maiwald et al., 2003b). They can also be visualized by bacterial fluorescent *in situ* hybridization using specific nucleic acid probes (Fredricks and Relman, 2001; Maiwald et al., 2003b). When examined by electron microscopy in human tissues, the bacteria have a distinctive shape and size and a "trilaminar" appearance of the cell envelope (Dobbins, 1987; Silva et al., 1985). The cell envelope consists – from inside to outside – of (i) a cytoplasmic membrane, (ii) a ~20 nm-thick cell wall with an inner polysaccharide and an outer peptidoglycan layer, and (iii) a symmetric outer membrane (Silva et al., 1985). The outer membrane is unlike other bacterial outer membranes and it has been suspected to be of human host origin (Silva et al., 1985). The polysaccharide (glycopeptide) layer confers reactivity with the PAS stain, which is used in the histopathological diagnosis of Whipple's disease. A corresponding gene cluster for the biosynthesis and export of extracellular polysaccharide has been found in the *Tropheryma whipplei* genome (Bentley et al., 2003).

Culture-based characteristics and growth conditions. *Tropheryma whipplei* can be propagated in cell culture with human fibroblasts (Raoult et al., 2000) and axenically in cell culture medium supplemented with extra amino acids (Renesto et al., 2003). It does not grow on any standard microbiological media. In fact, after the initial discovery by electron microscopy in 1961 that bacteria were associated with the pathogenesis of Whipple's disease, many culture attempts were undertaken and all failed or yielded contaminants (Dobbins, 1987). For decades, it was regarded as one of the classic uncultivated bacteria involved in human disease, along with *Treponema pallidum* and *Mycobacterium leprae*. The first *bona fide* culture isolate of *Tropheryma whipplei* was obtained from an infected aortic heart valve of a patient with endocarditis and is now the type strain, designated Twist-Marseille (CNCM I-2202) (Raoult et al., 2000).

Metabolism and metabolic pathways. Due to the difficulties with cultivation, biochemical tests are not currently used for the identification and characterization of *Tropheryma whipplei*. Information on metabolism has become available from the organism's genome sequence (Bentley et al., 2003; Raoult et al., 2003; Renesto et al., 2003). *Tropheryma whipplei* appears to be missing genes for the biosynthesis of some amino acids, as well as for some aspects of carbohydrate and energy metabolism. Genes for the biosynthesis of arginine, tryptophan, and histidine are completely absent, as are genes for the NADH dehydrogenase complexes and the tricarboxylic acid cycle. This renders *Tropheryma whipplei* an organism that is dependent on the supply of preformed nutrients from external sources, such as the human host.

Genetics and genomics. The genome sequences of two *Tropheryma whipplei* strains have been determined and analyzed (Bentley et al., 2003; Raoult et al., 2003). One of the strains, TW08/27, was obtained from cerebrospinal fluid (Maiwald et al., 2003b), and the other strain, the type strain Twist-Marseille, was obtained from a heart valve (Raoult et al., 2000). The sequence accession numbers are BX072543 and AE014184, respectively. Both genomes are markedly reduced in size and content, measuring slightly smaller than 1 Mbp (925,938 and 927,303 bp, respectively). By comparison, the known genomes of other actinomycetes range from about 2.1–10.1 Mbp (http://www.ncbi.nlm.nih.gov/). The genomic G+C content is 46% which is quite low considering that actinomycetes are generally high G+C-organisms. These features, plus the metabolic deficiencies, suggest that *Tropheryma whipplei* has undergone reductive genome evolution and occupies a host-dependent ecological niche.

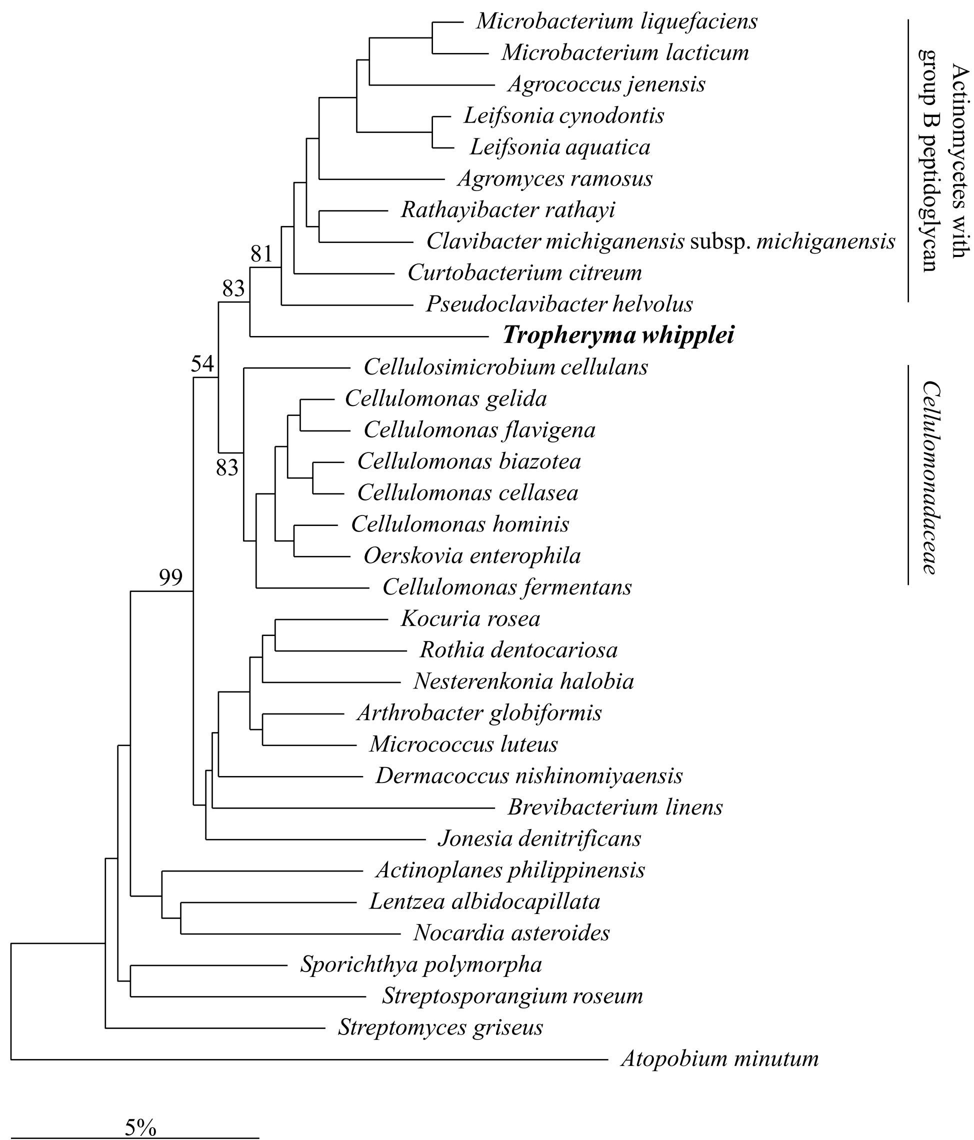

FIGURE 153. Phylogenetic tree displaying the relationships of *Tropheryma whipplei* to other actinomycetes. The scale bar represents five inferred nucleotide substitutions per 100 nucleotides. Numbers at branching points indicate bootstrap values. Modified and reprinted from Maiwald et al. (1996) with permission of the publisher. Strain designations (when available) and sequence accession numbers (in parentheses) are: *Actinoplanes philippinensis* DSM 43019^T (X93187), *Agrococcus jenensis* DSM 9580^T (X92492), *Agromyces ramosus* DSM 43045^T (X77447), *Arthrobacter globiformis* DSM 20124^T (M23411), *Atopobium minutum* ATCC 33267^T (M59059), *Brevibacterium linens* DSM 20425^T (X77452), *Cellulomonas biazotea* DSM 20112^T (X83802), *Cellulomonas cellasea* DSM 20118^T (X83804), *Cellulomonas fermentans* DSM 3133^T (X83805), *Cellulomonas flavigena* DSM 20109^T (X83799), *Cellulomonas gelida* DSM 20111^T (X83800), *Cellulomonas hominis* DSM 9581^T (X82598), *Cellulosimicrobium cellulans* DSM 43879^T (X83809), *Clavibacter michiganensis* subsp. *michiganensis* DSM 46364^T (X77435), *Curtobacterium citreum* DSM 20528^T (X77436), *Dermacoccus nishinomiyaensis* DSM 20448^T (X87757), *Jonesia denitrificans* DSM 20603^T (X83811), *Kocuria rosea* DSM 20447^T (X87756), *Leifsonia aquatica* DSM 20146^T (X77450), *Leifsonia cynodontis* (M60935), *Lentzea albidocapillata* DSM 44073^T (X84321), *Microbacterium lacticum* DSM 20427^T (X77441), *Microbacterium liquefaciens* DSM 20638^T (X77444), *Micrococcus luteus* (M38242), *Nesterenkonia halobia* DSM 20541^T (X80747), *Nocardia asteroides* DSM 43757^T (X80606), *Oerskovia enterophila* DSM 43852^T (X83807), *Pseudoclavibacter helvolus* DSM 20419^T (X77440), *Rathayibacter rathayi* DSM 7485^T (X77439), *Rothia dentocariosa* ATCC 17931^T (M59055), *Sporichthya polymorpha* DSM 46113^T (X72377), *Streptomyces griseus* (M76388), *Streptosporangium roseum* DSM 43021^T (X89947), and *Tropheryma whipplei* (X99636).

Despite the loss of genes for metabolic functions, the organism has a relative abundance of genes encoding cell surface molecules. About 15% of the organism's proteins are predicted to be located at the cell surface, and a significant proportion of these have no homologue in sequence databases. A new family of surface proteins was identified and termed WiSP (for *Tropheryma whipplei* surface proteins). Interestingly, the two genome-sequenced strains (Bentley et al., 2003; Raoult et al., 2003) are

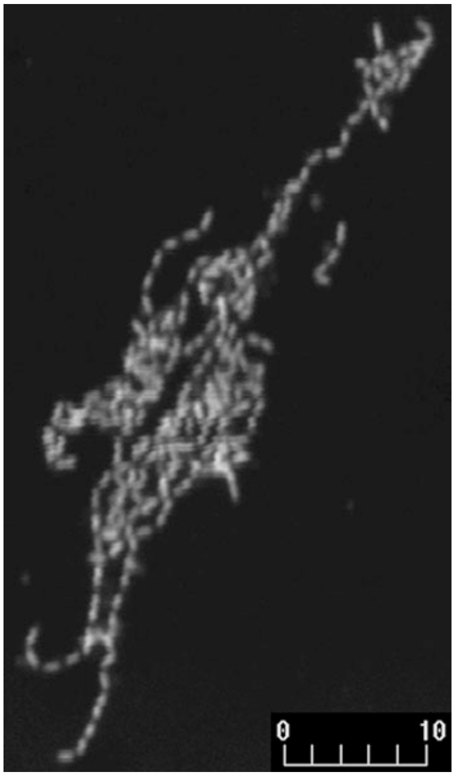

FIGURE 154. Photomicrograph of supernatant from a culture of *Tropheryma whipplei*. Bacteria were stained with YO-PRO-1 nucleic acid dye. Scale bar represents micrometers. Reprinted from Maiwald et al. (2003b) with permission from University of Chicago Press. Copyright 2003 by the Infectious Diseases Society of America.

distinguished by a large inversion of about 57% of the genome located between two WiSP genes. There are several apparent mechanisms by which *Tropheryma whipplei* creates genetic variability. It possesses several stretches of variable-number tandem repeat (VNTR) sequences and two unusual, large regions of non-coding repetitive DNA termed repeat clusters (RC) 1 and 2. VNTR sequences are known sources of antigenic and phase variation. In addition, one WiSP gene sequence that is embedded in a repeat cluster shows unusual, localized sequence hypervariation and is predicted to cause amino acid substitutions or frameshift mutations. Both the abundance and variability of surface molecules suggest that the organism possesses mechanisms to escape the host immune response.

Comparative genomic hybridization with a DNA microarray derived from the type strain Twist-Marseille using the DNA of 15 other isolated strains revealed remarkably little variation in gene content between different strains, with the percentage of conserved genes ranging between 97.8% and 99.9% (La et al., 2007). WiSP protein genes were significantly overrepresented among the divergent genes. The single strain with the lowest degree of conservation had a single deletion of 17 adjacent genes (19,052 bp) located between two WiSP genes. These findings indicate that the genome of *Tropheryma whipplei* is conserved and lacks exogenous genetic exchange to a similar degree as that of other small-genome, host-dependent organisms, that genomic variation between *Tropheryma whipplei* strains is derived mostly from WiSP gene differences, and that WiSP genes can act as "hot spots" for genomic rearrangements.

Strain typing. Differences between individual *Tropheryma whipplei* strains were first recognized in the 16S–23S rRNA intergenic spacer sequence (Hinrikson et al., 1999; Maiwald et al., 2000). At the present time, seven spacer types have been described and designated types 1–7 (Geissdörfer et al., 2001; Hinrikson et al., 1999; Maiwald et al., 2000). Most types only differ by a few nucleotides along the 293–294 bp spacer sequence. Types 1 and 2 are most common; the ratio is about 1:2 (type 1:type 2) in patients from Europe and North America (Maiwald et al., 2000). The other types are rare. The same spacer type is generally found in different sample types and at different time points from the same patient, which suggests systemic dissemination of individual *Tropheryma whipplei* strains in affected patients.

Differences at the nucleotide level are also found in a 23S rRNA insertion sequence that is common to the class *Actinobacteria* (the *Tropheryma whipplei* insertion sequence is 80 bp; those of other actinomycetes, 86–116 bp) and in the *groEL2* heat-shock protein gene sequence (Hinrikson et al., 2000; Morgenegg et al., 2000). The possibility of typing by VNTR sequence analysis was explored in one study (Maiwald et al., 2003a). Samples from 11 patients were examined at three VNTR loci and for their 16S–23S rRNA spacer type. A distinct typing pattern was found for each individual *Tropheryma whipplei* strain, however, given the unstable nature of VNTRs, it remains unclear if the patterns remain stable during the course of the disease or during culture passages. A more comprehensive typing method was developed with microarray-based comparative genomic analysis (La et al., 2007). Of 16 analyzed strains, all were individually distinguishable based on their hybridization patterns. However, the approach, as published, depended on the availability of cultivated strains as opposed to the suitability of the other methods for fixed and unfixed tissues and body fluids, as well as culture material.

Antigenic structure. Antibodies in patients' sera and antibodies raised in rabbits or mice against cultivated *Tropheryma whipplei* can be used to detect bacterial material in histological sections and in tissue culture cells (Baisden et al., 2002; La Scola et al., 2001; Raoult et al., 2000). Cultivated bacteria have also been tested for their usefulness as a source of antigen in a serological assay with patients' sera (Raoult et al., 2000). However, sensitivity and specificity were limited: elevated IgM titers were detected in 7 of 9 sera from patients and 3 of 40 sera from controls and elevated IgG titers in 9 of 9 patient sera and 29 of 40 controls.

Immunoblotting of whole-cell extract from a cultivated *Tropheryma whipplei* strain with mouse polyclonal antiserum showed strongly reactive bands at 213, 110, and 85 kDa (La Scola et al., 2001). A mouse monoclonal antibody to an 84 kDa immunodominant antigen of *Tropheryma whipplei* was raised and found to be specific when tested with control bacteria (Liang et al., 2002). However, in both studies, the nature of the antigens was not further examined.

Genome sequencing has revealed the WiSP family of proteins as unique to *Tropheryma whipplei* (Bentley et al., 2003; Raoult et al., 2003). Members of the WiSP family differ considerably in size (103–2308 aa), but are characterized by several common features such as common N-terminal or C-terminal domains or beta-strand motifs. They are likely to be important major antigens, but no data are available concerning antigenicity of WiSPs and the human immune response against these proteins.

A proteomic approach has been applied in an effort to characterize antigens for use in serological tests (Kowalczewska et al.,

2006). Proteins of cultivated *Tropheryma whipplei* organisms were separated with two-dimensional gel electrophoresis, immunoblotted with patient and control antisera, and analyzed by mass spectrometry. Twenty-three candidate antigens were identified, of which six were recognized significantly more frequently by patient than control antisera, and 17 recognized only by some patient antisera. However, no single antigen had sufficient sensitivity and specificity to be used alone in a serological test, so it was proposed to use a combination. Only one of the proteins was predicted to be located at the cell membrane; most were predicted to be cytoplasmic proteins.

Antibiotic sensitivity. Antibiotic therapy for *Tropheryma whipplei* infection is primarily based on empirical observations (Dobbins, 1987). The disease responds well initially to tetracyclines, but since tetracyclines do not penetrate the blood-brain barrier well, patients tend to suffer from relapses affecting the central nervous system. Currently, treatment of choice is an initial two-week intravenous regimen with either penicillin plus streptomycin or with a third-generation cephalosporin followed by oral therapy with trimethoprim-sulfamethoxazole for 1 year or more (Maiwald et al., 2010).

Laboratory data on antibiotic susceptibilities have become available from work with cultivated *Tropheryma whipplei* strains. Growth in the presence of antibiotics was assessed with real-time PCR. In co-culture with fibroblasts, the bacterium appears sensitive to doxycycline, macrolides, penicillins, rifampin, teicoplanin, and trimethoprim-sulfamethoxazole, variably sensitive to imipenem, and only moderately sensitive or resistant to cephalosporins, fluoroquinolones, and vancomycin (Boulos et al., 2004). In axenic medium, the results were very similar to those in cell culture, except that *Tropheryma whipplei* was sensitive to ceftriaxone and vancomycin (Boulos et al., 2005). Interestingly, the target gene for trimethoprim action, dihydrofolate reductase, is absent from the *Tropheryma whipplei* genome, so that the activity of the trimethoprim-sulfamethoxazole combination is presumably based solely on its sulfamethoxazole component.

Pathogenicity. *Tropheryma whipplei* is the agent of Whipple's disease, a chronic systemic illness of humans affecting the intestinal tract as well as multiple other organs. Intestinal manifestations most commonly include a malabsorption syndrome with weight loss, diarrhea, and abdominal pain. The onset is protracted, usually over 1–2 years, and is often preceded by several years of episodes of arthralgias or arthritis. The intestinal lamina propria as well as intestinal and mesenteric lymph nodes are filled with lipid deposits and with macrophages containing PAS-positive bacterial inclusions. Among the various other manifestations of Whipple's disease are central nervous system disease with dementia and movement disorders, joint manifestations (arthralgias and arthritis), and "blood culture-negative" endocarditis (Maiwald et al., 2010; Marth and Raoult, 2003).

The virulence mechanisms of *Tropheryma whipplei* are largely unknown; in particular, it is unclear how the bacterium enters the human body and human tissues, how it establishes infection, and how it avoids immunological clearance. It is thought that host immunological factors play a role in the establishment of disease. Clearly defined immunological defects have not been identified, but patients with Whipple's disease have quantitative abnormalities in certain immunological functional parameters. For example, peripheral blood monocytes of Whipple's disease patients, when challenged with various stimuli, show quantitative imbalances in cytokine secretion when compared to controls (Marth et al., 2002).

Genes with a presumed function in pathogenesis are scarce in the *Tropheryma whipplei* genome. Two genes that are predicted to encode surface proteins are similar to a gene (*tadA*) required for pilus-mediated tight adherence of the pathogen *Actinobacillus actinomycetemcomitans*; gene homologues are also widely distributed among other bacteria. In addition, the abundance of predicted surface molecules, many of which are novel and variable, suggests that *Tropheryma whipplei* has mechanisms to escape immunologic recognition and clearance.

Ecology and epidemiology. The questions of natural habitat and mode of acquisition of *Tropheryma whipplei* are unresolved. There is a moderate overrepresentation of outdoor workers (farmers, carpenters) among patients with Whipple's disease (Dobbins, 1987). In addition, *Tropheryma whipplei* sequences have been detected by PCR in sewage samples (Maiwald et al., 1998). This might be suggestive of an environmental habitat. On the other hand, *Tropheryma whipplei* DNA has been detected in saliva and in intestinal specimens of healthy people (Ehrbar et al., 1999; Street et al., 1999), suggesting that *Tropheryma whipplei* may be a human commensal that becomes pathogenic when the control by host immunity lapses.

There is also debate about whether *Tropheryma whipplei* replicates as an intracellular or extracellular organism. While macrophages with PAS-positive intracellular inclusions are the histopathologic hallmark of Whipple's disease, intact bacteria undergoing binary division are consistently seen in extracellular locations by electron microscopy (Silva et al., 1985). In addition, the rRNA of *Tropheryma whipplei* (presumably from metabolically active bacteria) can be detected in extracellular locations (directly underneath the intestinal epithelial basement membrane) by fluorescent *in situ* hybridization (Fredricks and Relman, 2001). *Tropheryma whipplei* has been found to replicate inside monocytes and macrophages, in a manner dependent on the presence of the cytokine interleukin-16 (Desnues et al., 2005). Given that *Tropheryma whipplei* replicates in axenic medium supplemented with extra amino acids (Renesto et al., 2003), it is quite conceivable that it replicates directly underneath the intestinal basement membrane in the lamina propria, supplied by a rich influx of nutrients from the intestinal lumen. However, such requirements might also be met if it replicates in an environment in association with a polymicrobial community.

Enrichment and isolation procedures

Tropheryma whipplei has been isolated from infected human heart valves, ocular vitreous fluid, duodenal biopsy specimens, peripheral blood, and cerebrospinal fluid (Fenollar et al., 2003; Maiwald et al., 2003b; Raoult et al., 2000, 2001). However, so far, this has only been achieved in specialized research laboratories. Culture-based approaches are not suitable for routine diagnostic purposes in clinical microbiology laboratories. Cell lines that have supported cultivation are HEL and MRC-5 primary human embryonic lung fibroblasts (CCL-34 and CCL-171, respectively; ATCC, Manassas, VA, USA) (La Scola et al., 2001) and primary human foreskin fibroblasts (Maiwald et al., 2003b). Minimal essential medium (MEM) supplemented with

fetal calf serum and L-glutamine can be used to cultivate and maintain fibroblast cell monolayers and to propagate *Tropheryma whipplei* in association with these cells (La Scola et al., 2001). One culture passage may require about 2–4 weeks. For primary isolation from clinical specimens, shell vials (as for viral cultures) are helpful (La Scola et al., 2001). Pre-incubation with antibiotics (amphotericin B, colistin, and cephalothin or ciprofloxacin) is useful for isolation from contaminated duodenal tissue (Fenollar et al., 2003; Raoult et al., 2001). Growth of *Tropheryma whipplei* in culture can be assessed by qualitative or quantitative PCR for *Tropheryma whipplei* nucleic acids, by staining with PAS reagent or YO-PRO fluorescent nucleic acid stain (Figure 154), by fluorescent *in situ* hybridization, and by immunofluorescent staining using specific antisera (La Scola et al., 2001; Maiwald et al., 2003b; Raoult et al., 2000). Bacteria are found both in the fibroblast cell monolayers and in the culture supernatant. Medium suitable for the propagation of *Tropheryma whipplei* in cell-free conditions can be made from tissue culture medium by supplementation with 10% fetal calf serum, 1% L-glutamine, and 1% human non-essential amino acids (Renesto et al., 2003). So far, this recipe has supported the growth of several strains after primary cell-based isolation and allowed the primary isolation of one strain from a heart valve sample (Renesto et al., 2003).

Differentiation of the genus *Tropheryma* from other genera

Standard microbiological tests are generally unsuitable for identification and differentiation of the genus *Tropheryma* from other genera. In human specimens, the detection of PAS-positive inclusions in macrophages by histology or cytology, followed by confirmation of typical bacterial morphology by electron microscopy, is considered proof of *Tropheryma whipplei* infection (Maiwald et al., 2010). Although some other genera (e.g. *Mycobacterium*, *Rhodococcus*) may stain PAS-positive, no known organisms associated with PAS-positive inclusions have the same small, regular, rod-shaped appearance with a symmetric outer membrane when viewed by electron microscopy (Silva et al., 1985). The most appropriate method for bacterial identification, however, is PCR followed by sequencing. Suitable targets are the 16S rRNA gene or 16S–23S rRNA intergenic spacer because comparative sequence information is readily available. Primers for the 16S rRNA gene include *Tropheryma whipplei*-specific tw1013f (5′-AGAGATACGCCCCCCGCAA) and tw1243r (5′-ATTCGCTCCACCTTGCGA), which are modified versions (without extra restriction enzyme recognition sites) of the primers pW3FE and pW2RB published by Relman et al. (1992) and yield a 266 bp amplification product. Alternatively, any bacterial broad-range primers spanning a longer 16S rDNA segment may be used (Maiwald, 2011). Primers spanning the 16S–23S intergenic spacer are *Tropheryma whipplei*-specific tws3f (5′-CCGGTGACTTAACCTTTTTGGAGA) and tws4r (5′-TCCCGAGGCTTATCGCAGATTG); they yield a 490 bp amplification product (Hinrikson et al., 1999). Another suitable target is a repetitive sequence element found on the *Tropheryma whipplei* genome (Fenollar et al., 2004). The primers are 53.3F (5′-AGAGAGATGGGGTGCAGGAC) and 53.3R (5′-AGCCTTTGCCAGACAGACAC) and the product size is 164 bp. It should be emphasized that visualization of amplification products on gels is not sufficient for identification. With any of the PCR assays, sequencing is necessary.

Taxonomic comments

Relman et al. (1992) proposed the name "*Tropheryma whippelii*" for the bacterium, after molecular identification directly from human tissue using bacterial broad-range PCR, sequencing, and phylogenetic analysis. The name contains the Greek words for "nourishment" and "barrier" to describe the malabsorption syndrome that is commonly associated with Whipple's disease and honors George H. Whipple, the American pathologist who first described the disease (Whipple, 1907). The bacterium was then formally described after a cultivated isolate became available (La Scola et al., 2001; Raoult et al., 2000). In the formal description, latinization of the species name resulted in a change to *whipplei* (La Scola et al., 2001).

Tropheryma whipplei is not closely related to any other bacterium on the basis of its 16S rRNA gene sequence or its genome contents. It is a member of the phylum *Actinobacteria*. The order and family designations of the genus *Tropheryma* have not been formally established. The National Center for Biotechnology Information (NCBI) website (http://www.ncbi.nlm.nih.gov/), in its Taxonomy Browser, lists class *Actinobacteria*, subclass *Actinobacteridae*, order *Actinomycetales*, suborder *Micrococcineae*, family *Cellulomonadaceae*, genus *Tropheryma*, although this is not based on any formal publication. According to a thorough description of the class *Actinobacteria* (Stackebrandt et al., 1997), the families most closely related to *Tropheryma whipplei* are *Cellulomonadaceae* (with group A peptidoglycan) and *Microbacteriaceae* (with group B peptidoglycan), both in the suborder *Micrococcinae* (since elevated to order *Micrococcales* in the roadmap to the present volume). However, the relationships of *Tropheryma whipplei* to both families are quite distant, with more than 8% 16S rRNA gene sequence divergence (Maiwald et al., 1996).

Miscellaneous. Unlike many other bacterial diseases, anatomic and surgical pathology are most commonly involved in the laboratory diagnosis of Whipple's disease (using histopathology, cytology, and electron microscopy). Clinical microbiology has become increasingly involved since the early 1990s, with the availability of PCR tests. There are four main diagnostic laboratory methods for Whipple's disease: (i) histology from paraffin-embedded tissue specimens (commonly intestinal biopsies) using the PAS stain, (ii) cytology from body fluids using the PAS stain, (iii) electron microscopy looking for typical bacteria in tissues or body fluids, and (iv) diagnostic PCR for DNA of *Tropheryma whipplei*. Most PCR assays are based on the 16S rRNA gene sequence of *Tropheryma whipplei* as originally published by Relman et al. (1992); some are based on alternative sequences, such as a repetitive sequence element found in the *Tropheryma whipplei* genome (Fenollar et al., 2004). While PCR testing has become important as a second-line confirmatory test for histopathology on intestinal biopsy specimens, it can also be used as a first-line test on extra-intestinal specimens such as cerebrospinal fluid, joint fluid, and ocular vitreous fluid (Maiwald et al., 2010).

List of species of the genus *Tropheryma*

1. **Tropheryma whipplei** La Scola, Fenollar, Fournier, Altwegg, Mallet and Raoult 2001, 1478[VP]

whip′ple.i. N.L. gen. masc. n. *whipplei* of Whipple, after George H. Whipple, the pathologist who described the disease that became known as Whipple's disease.

Since *Tropheryma whipplei* is the only species of the genus, the identification criteria given in the section on the genus *Tropheryma* apply equally to the species. Since the organism does not grow on standard microbiological media and is nonreactive in conventional biochemical tests, identification is best achieved using PCR and nucleic acid sequence analysis. *Tropheryma whipplei* is commonly found in the intestinal mucosa of patients with Whipple's disease and visualized by histopathology. Cultivated isolates have been obtained from heart valves, peripheral blood, ocular vitreous fluid, intestinal biopsies, and cerebrospinal fluid. The type strain Twist-Marseille (CNCM I-2202) was isolated from the aortic valve of a patient with endocarditis (La Scola et al., 2001; Raoult et al., 2000) and represents the first successful culture of the organism after several decades of unsuccessful attempts by various researchers.

DNA G+C content (mol%): 46 (genome sequence).

Type strain: Twist-Marseille, CNCM I-2202.

Sequence accession no. (16S rRNA gene): AF251035.
